The following description may be taken as that of Ives's process by the trichromatic theory of colour-vision every colour in nature can be accounted for by the mixture of two or three of the three-colour sensations, red, green and blue, to which the eye is supposed to respond. Thus a mixture of a red and green sensation produces the sensation of yellow; of a green and blue, that of a blue-green; of red and blue, that of purple; and of all three, that of white. For the sensations we may substitute those colours which most nearly respond to the theoretical sensations without any material loss of purity in the resulting sensation. We must take the spectrum of white light as the only perfect scale of pure colours. It has been proved that the red sensation in the eye is excited by a large part of the visible spectrum, but with varying intensities. If, then, we can on a photographic plate produce a developed image of the spectrum which exactly corresponds in opacity and position to the amount of red stimulation excited in those regions, we shall, on illuminating a transparent positive taken from such a negative with a pure red light, have a representation of the spectrum such as would be seen by an eye which was only endowed with the sensation of red. Similarly, if negatives could be taken to fulfil the like conditions for the green and for the blue sensations, we should obtain positives from them which, when illuminated by pure green and blue light respectively, would show the spectrum as seen by an eye which was only endowed with a green or a blue sensation. Evidently if by some artifice we can throw the coloured images of these three positives on a screen, superposing them one over the other in their proper relative positions, the spectrum will be reproduced, for the overlapping colours, by their variation in intensity, will form the colours intermediate between those used for the illumination of the positives. For the purpose of producing the three suitable negatives of the spectrum, three light-filters, through which the image has to pass before reaching the photographic plate, have to be found. With all present plates these are compromises. Roughly speaking, the screens used for taking the three negatives are an orange, a bluish-green and a blue. These transmit those parts of the spectrum which correspond to these colours. When these are obtained an image of a coloured object can be reproduced in its true colours.

Abney devised sensitometers for determining the colours of the screens to be placed before the lens in order to secure the three-colour negatives which should answer these requirements. Their production depends upon the same principles indicated as necessary for the correct rendering in monochrome of a coloured object. When the sensitometer takes the form of glasses through which light is transmitted to the plate, the luminosities of the coloured lights transmitted are determined, and also their percentage composition in terms of red, green, and blue lights, and then the are deduced the luminosities in terms of red, green and blue. For ascertaining what screen should be used to produce the red negative the luminosity transmitted through each glass is so adjusted that the luminosity corresponding to the red component is made equal by rotating a disk with correct apertures cut out close to the row of glasses. This gives a sensitometer of equal red values. A coloured screen has to be found which when placed in front of the red light, produces the false negatives on one plate, since only in this way can they be developed and the densities increased together. (For commercial work the negatives often cannot be taken on the same plate, as it would make the plate too large to manipulate. The plates have to be moved in an ordinary paper chamber, H, in repeating back, bringing successively three different portions of the plate opposite the lens. It is convenient to have a slide, in front of which a holder containing the three screens can be fixed, which will then be close to the plate; such a one has been devised by E. Sanger-Shepherd. The light passes through them one by one as the plate is moved into the three positions. The three exposures are given separately, after which the plate is ready for development.) The three negatives are of necessity a source of trouble at times, particularly in the case of landscapes, for the lighting may vary and the sky may have moving clouds, in which case the pictures would show variations which should not exist. Sanger-Shepherd has pointed out that the negatives by which the three images are thrown side by side on the plate. Thus any movement in the picture affects all three negatives alike. Altmann has also introduced the device of an achromatic "tuners" which alter in a larger angle than that of Sanger-Shepherd. The next point is the exposures which should be given through each screen. This can be done by placing in front of the plate and extending its whole length a table of gradations through which the light from the sun-illuminated white card passes, as well as through the screens. In the case of the three-exposure camera the times of exposure are varied till the densities of the image of the gradation appear the same in both of the three images. In the case of the ordinary camera, the light reaching the plate through the screens is altered by cutting off with a shutter more or less of the lens used. As the plates employed for the purpose of the three-colour negatives must be sensitive to every colour, the ordinary dark-room light should be most cautiously used. If used at all, it should be very feeble and development must be carried out in a dish with a cover to it. The plate is manipulated in the usual way.

Joly's Process.—Professor J. Joly, of Dublin, in 1897 introduced a colour process by which an image in approximately natural colours could be thrown upon a screen by an optical lantern, only one transparency being employed, instead of three, as in the Ives process. A "taking" screen was ruled with alternating orange, blue-green and blue lines \( \frac{1}{8} \) to \( \frac{3}{4} \) in. apart, touching one another and following one another in the above order. When such a screen was placed in front of a sensitive plate in the camera, and exposure made to the image of a coloured object, there were practically three negatives on the same plate, each being confined to the area occupied by lines of the same colour. The shades of colour and the depth of the colours used in ruling depended on the brand of plate. When a perfect triune negative was obtained, a transparency was made from it, and in contact with this was placed a screen ruled with lines the same distance apart, but of the colours corresponding to the three colour sensations, namely red, green and blue. The red lines were made to fall on the image taken through the orange lines, the green on that of the blue-green, and the blue or violet on that of the blue. On the screen there are practically three differently coloured images, one for each transparency. The eye blends the different colours together and a picture is seen in approximately the correct colours of the original.

Autochrome.—A very remarkable process, founded on J. Joly's process, was introduced in 1907 by A. Lumière et ses Fils of Lyons. Starch grains of very minute size, some of which were dyed with a red stain, a second portion with a green, and a third portion with a blue, are mixed together in such proportions that a fine layer of them appears grey when viewed by transmitted light. Under a magnifying glass the grains are coloured, but owing to the want of focus in the eye the colours blend one with the other. Such a layer is embedded on the surface of a glass plate in a waterproof vehicle, and a film of sensitive emulsion held in situ in some material, the composition of which has not been published, covers this layer. When such a plate is placed in the camera, with the back of the plate next the lens, the light passes through the coloured granules, and again we have three negatives on one plate, but instead of each negative being represented by lines as in the Joly process they are represented by dots of silver deposit. Owing to the way in which the three-coloured film is prepared, it is evident that a positive taken from such a negative could not be backed with granules of the right colour, as the granules are placed at random in the layer. Lumière, to overcome this difficulty, converted the negative into a positive by a very ingenious way. The plate was developed by the gallic acid and ammonium in the usual way, but instead of fixing it was plunged into a solution of potassium permanganate and sulphuric acid. This dissolved all the silver that had been deposited during development and left a film of unalterable silver salt. On looking through the plate the colours of the coloured layer coming through the different dots where the silver was at
first deposited appeared in view, and the image was the image in colour of the object photographed. The plate after being washed was taken into the light and redeveloped with an alkaline developer, which converted the sensitive salt of silver to the metallic state. The image now consisted of black particles of silver and the coloured image. The plate was next fixed in hypo-phosphate of soda to remove any unreduced silver salt that might be left, and the picture after washing was completed. The coloured image so obtained is a very close representation of the true colours, but as the “taking” screen is the same as the “viewing” screen some small variation must result.

Positives in Three Colours.—Ives was the first to show that a transparency displaying approximately all the colours in nature could be produced on the same principles that underlie the three-colour printing. This he effected by printing each of the three negatives, produced for his triple projection process as already described, on gelatine films sensitized by bichromate of potash. Each of the three transparent films was dyed with a colour complementary to the colour of the light which he transmitted through the positives when used for projection. Thus the red positive he dyed with a blue-green dye, the green positive with a purple dye, and the blue positive with a yellow dye. These three films, when superposed, gave the colours of the original object. Sanger-Shepherd has made the process a commercial success (see Process) and produces lantern slides of great beauty, in which all colours are correctly rendered. Instead of using a dye for the “red” transparency, he converts the silver image of a positive image into an iron salt resembling Prussian blue in colour. (W. DE W. A.)

II.—Photographic Apparatus

Photographic apparatus consists essentially of the camera with lens and stand, lens shutters, exposure meters, prepared plates for the production of negatives or transparencies, sensitive papers and apparatus for producing positive prints, direct or by enlargement. Besides these there are many subsidiary accessories.

Since the introduction of highly sensitive dry plates and their extended use in hand cameras, the art and practice of photography have been revolutionized. Numerous special forms of apparatus have been created suitable for the requirements of the new photography, and their manufacture and sale have become important industries. The value of the exports of photographic materials from the United Kingdom in 1900 was £2,716. The most important improvement has been in the construction of anastigmatic lenses, which, having great covering power, flatness of field, and freedom from astigmatism, can be worked with very much larger apertures than was possible with the earlier forms of rectilinear or aplanatic lenses. The increased rapidity of thating thus gained has rendered it easy to photograph objects in very rapid motion with great perfection. This has encouraged the construction of the very light and compact hand cameras now so universally in use, while, again, their use has been greatly simplified by improvements in the manufacture of sensitive plates and films and the introduction of light, flexible, sensitive films which can be changed freely in daylight. The introduction in 1897 of Messrs Lumière's “Autochrome” process of colour photography has also been a great advance, tending to popularize photographic work by the facility it offers for reproducing objects in the colours of nature.

The Camera.

Historical.—The camera obscura (q.v.) was first applied to photographic use by Thomas Wedgwood between 1752 and 1802. No description of this camera is available, but it was probably one of the sketching cameras then in use. In 1812 W. H. Wollaston found that by using a meniscus lens with a concave surface towards the object and the convex towards the screen, a diaphragm being placed in front, the projected image of the camera obscura was greatly improved in sharpness over a larger field. The first photographic lenses made by V. and Ch. L. Chevalier in Paris (1830–1840) were on this principle. The photographic camera in its simplest form is a rectangular box, one end of which is fitted to carry a lens and the opposite one with a recess for holding the focusing screen and plate holders, these ends being connected by a rigid or expanding base-board and body, constructed to keep out all light from the sensitive plate except that passing through the lens. In 1816 Joseph Nicéphore Niepce, of Chalon-sur-Saône, who had previously made a little camera, or artificial eye, with a box six inches square fitted with an elongated tube carrying a lenticular glass. There are now in the Chalon Museum cameras of his with an iris diaphragm for admitting more or less light to the lens; some with an accordion bellows, others with a double expanding rigid body for adjusting the focus. The iris diaphragm was adopted later by Chevalier for his photographic lenses. In 1835 W. H. Fox Talbot constructed simple box cameras for taking views of his house on sensitive paper, and claimed them as the first photographs of a building (Phil. Mag. 1839, 14, p. 206). Fr. von Kobell and C. A. Steinheil, early in 1839, made a camera with an opera glass lens for taking landscapes on paper. Later in 1839 J. W. Draper successfully used a camera for his daguerreotype experiments made of a spectacle lens, 14 in. focus, fitted into a cigar box. He also used a camera fitted with a concave mirror instead of a lens. Similar cameras were constructed by A. T. Wolcott (1840) and R. Beard (1841) for reversing the image in daguerreotype portraits. They have also been recommended by V. Zenger (1872) and D. Mach (1890) for scientific work.

L. J. M. Daguerre’s camera, as made by Chevalier in 1839 for daguerreotype, was of Niepce’s rigid double box type, fitted with an achromatic meniscus lens with diaphragm in front. Wollaston’s principle, the back part with the plate moving away from the lens for focusing, and fixed in its place with a thumb-screw. This expanding arrangement enabled lenses of different focal lengths to be used. With modifications cameras of this type were in use for many years afterwards for portrait and studio purposes. For work in the field they were found inconvenient, and many more portable forms were brought out, among them G. Knight’s and T. Oettewill’s single and double folding cameras (1853), made collapsible with hinges, so as to fold on to the base-board. Cameras with light bodies made of waterproof cloth, &c., also came into use, but these were superseded by cameras with collapsible bellows—body of leather, which, invented by Niepce, were used in France, in 1839, by Baron A. P. de Ségurier and others for daguerreotype. The first record of them in England is, apparently, J. Atkinson’s portable stereoscopic camera of parallel-side bellows form (Ph. Journ. 1857, 3, p. 261), which was soon followed by C. T. H. Kinnear’s lighter conical form, made by Bell of Edinburgh (Ph. Journ. 1858, 4, p. 166). They have since been made in various patterns, conical, oblong and square, by F. Meagher, G. Ifare and others, and are still, in modified forms, in general use as studio, field or hand cameras. When wet collodion plates were used many cameras were fitted with arrangements for developing in the field.

Information on these and other early cameras will be found in the photographic journals, in C. Fabre’s Traité encyclopédique de photographie, vol. i., and in J. M. Eder’s Ausführliches Handbuch der Photographie, 2nd ed., vol. i., pt. ii.

The distinctive feature of present day photography is the world-wide use of the hand camera. Its convenience, the ease with which it can be carried and worked, and the remarkably low prices at which good, useful cameras of the kind can be supplied, concurrently with improvements in rapid sensitive plates and lenses, have conducd to this result. It has also had a valuable educational influence in quickening artistic perception and scientific inquiry, besides its use in depicting scenes and passing events for historical record. Some portable cameras had been made by B. G. Edwards (1855), T. Scaife (Pistolgraph, 1858), A. Bertsch (1860), T. Oettewill (1861), and others, but it was not until rapid gelatin dry plates were available in 1881 that T. Bolas brought out his “detective” camera (Ph. Journ. 1881, p. 59). It consisted of a double camera (one as finder, the other for taking the picture) enclosed in another box, suitably covered, which also contained the double-plate carriers and had apertures
PHOTOGRAPHY

in front of the viewing and taking lenses. In another form the finder was omitted. A month later A. L. Lisseau and J. B. Germeull-Bonnaud patented an opera glass camera. Various forms of magazines and rolls of camera followed, among them A. Puphredy's "Repeating Camera" (1835), W. Krugener's camera (book form, 1888), and others in collapsible or box forms disguised as books, watches, &c., but they did not come into general use before 1888, when the Eastman Company of Rochester, U.S.A., brought out their very portable roll-film cameras, now known under the trade name of "Kodak." The manufacture of these and other light hand cameras has since become a very important and flourishing industry in Great Britain, Germany, France, and the United States. It is noteworthy that the most modern form of hand camera, the reflex, goes back to an early type of portable camera obscura, figured by Johann Zahn in 1686, in which a mirror was used for reflecting the image on to a horizontal focusing screen, at the same time reversing it. The first photographic camera on this principle was T. Sutton's (1860), which has served as a basis for many subsequent developments. A. D. Loman's (1859) and R. Krugener's (1891) were early examples of the hand camera type, but great improvements have since been made.

Modern cameras differ so much in details of improved construction that only a few of the more important requirements can be noticed. A camera should be well and strongly made of seasoned wood or of brass, so that when set up or adjusted any slight movement of the lens in respect to the sensitive plate. The front and back of the camera should be normal and vertical, and the angle of the lens perpendicular to the centre of the plate, but adjustments are usually made by vertical and lateral adjustments on the camera front for raising the lens to take in less foreground or vice versa, or for moving it right or left, the latter becoming a vertical movement when the camera has been turned on its side. In the Adams "Identico" camera the lens and finder are rotated together on the rising front according as the camera is used horizontally or vertically, the finder showing in either case the identical view. The greatest convenience in the tripod viewfinder is that the most modern field cameras are fitted with a swing-back or swing-front and sometimes both. A swing-back is necessary for bringing back the plate to the vertical position, so as to prevent divergence of vertical lines, when the camera is in front, in which case it is tilted, answers the same purpose, provided the camera is kept level. If further tilting is necessary, when taking high buildings &c., the swing-back and front may both be required, but must be kept vertical and parallel and the effect is that of an abnormal raising front. Many modern cameras are fitted with a double rising front. The vertical and side swings are also essential for giving the definition of objects at different distances from the camera, but are more effective, when made in one swing, and preferably are round the central horizontal or vertical axis of the back or front, but are affected by simple inclination of the back or lens front on a hinge. When the rising front is used a spring is necessary to stop it down to obtain good definition over the extended area of the picture. A slight inclination of the lens may also be useful in adjusting the focus. The camera and plate carriers must be perfectly clean inside, and the glass surfaces made dead black to prevent reflections from bright spots being thrown on the plate. The back varnish used, preferably of shellac and lampblack, must be kept free from dirt, must have no deleterious effect on the plate. Although the weight and bulk are increased it is convenient to have the camera square and fitted with a reversible back, so that the greatest length of the plate may be horizontal or vertical, as desired. Many cameras are of reversible type, and can face both sides, but the view cameras (as French) with bellows, are of this type. In some French cameras the back part of the camera with the bellows is reversible, to be used upright or horizontal.

Focusing.—The earlier cameras were focused by drawing out the back or swing, and adjusting the nearness of the plate by moving the base-board. When bellows came into use they were focused by an endless screw, and these are still used for large copying cameras. Most modern cameras are fitted with rack and pinion movements, usually operated by a lever either in front of the camera or on both. Many hand cameras, requiring to be brought to focus at once, are fitted with studs (infinity catches) which fix the front in focus for distant objects, nearer distances being noted on an engraved scale. In motion picture or still film cameras, the horizontal and vertical directions are adjusted by measurement. In hand cameras with fixed infinity focus, the necessary adjustments for distance of near objects are made on the lens mount. The focusing screen may be ruled with parallel lines running in a position of measurement perpendicular to the front and the verticality of the camera when photographing buildings or other objects with vertical lines. The distance from the lens on the focusing screen and from the sensitive plate in the dark slide must coincide exactly. This can be tested by measurement or by focusing a bright, well-defined object on the screen and then on a ground-glass screen. A small box placed in the back of the lens may be used. A level or other means of showing that the camera is level and the plate vertical should be attached to the camera, also a view meter or finder, showing the exact extent of the picture on the focusing glass. In some cameras the picture is viewed directly through a glass mounted at the back of the camera as it appears in a frame with cross wires on the rising front, adjusted to the size of the plate and the focus of the lens. The finders are practically small reflex cameras, easy to adjust in position, and have, in some instances, a window. A rectangular concave glass mounted on the camera is also a convenient form, it can be combined with a mirror for vertical observations. In Watson's new form is also arranged as a level and teleometer (B. J. A.). The plates should correspond exactly with that on the plate. When the rising front is used special arrangements have to be made to ensure the same in the absence of this, but in the finder and on the ground-glass. This is done in the "Adams Identoscope" (1908), which is fitted to the swing front and adjusted by a lever to follow the movement of the lens.

The dark-sides or backings, holding sensitive plates, are made either single or double, the former usually for wet plates, the latter for dry plates. The ordinary book-form double dark-slide has been in use since the early days of calotype paper money, and contains two plates separated by a blackened metal plate; three of them usually form a set, the shutters being numbered 1 to 6, the odd numbers on the opening side. Inner shutters can be used for smaller plates if desired. The slides should fit really the edge of the glass, and the shutters must slide smoothly in and out. They must be perfectly light-tight, the corner joints, the hinges in the shutters, and the openings in the sides and top of the book are usually made requiring careful examination or protection by metal plates. The shutters of dark-sides are either jointed or solid and removable; the former is perhaps the more convenient, but both forms may become liable to let in light. Various forms of solid slides, single and double, are now made in wood or metal, or of wood for the frame and metal for the shutters; they are lighter, more compact and less liable to admit light to the plates. In some cases one slide can suffice for the two benches for several plates, the envelopes at the edges of the plate can be fitted to the "Wishart-Mackenzie" slide, the "Victrix" and other similar ones, or contained in a single packet, as in the "Premo FilmPack," and similar arrangements can be made. The packets of films are made of light cardboard, and afford a good saving of bulk and weight (fig. 11). One side of these boxes are also a convenient way of carrying sensitive celluloid films in lengths of six to twelve feet, and are sold for round spools, which can be changed in daylight. Changing boxes for holding the films is made of celluloid films in sheets, are used with some magazine and other cameras. They are arranged so that the film in a place in the dark-slide and the plates are changed automatically so that exposed plates are placed in order successively at the back, a fresh plate going forward for exposure and the number of the exposure being recorded at the same time.

Studio cameras, for portraiture, are usually of the square bellows type, of solid construction, to take large and heavy lenses; adjustable from front and back with rack and pinion movements, to enable the camera to be brought up to the plate without the light being enlarged. They are generally fitted with repeating backs, allowing two or more exposures to be made on one plate. The backs are square or reversible, so that the plates can be used upright or horizontal, with the table-top usually having vertical and horizontal angular movements. Large cameras with long extension for copying purposes are made in many forms with special arrangements for the position of the table-stand, and are mounted on substantial table-stands with screw adjustments for obtaining the various positions above noted, and also a rectilinear traversing movement right or left. All these stands should be absolutely rigid and free from tremor. Process cameras are, however, sometimes mounted,

Together with the copying board, on swinging stands, to avoid the effects of vibration.

Folding and Hand cameras include cameras of the Hare and Meagher types for outdoor work and general purposes on plates 15 in. X 12 in., to 8½ in. X 6 in., and in lighter forms from 6½ in. X 4½ in. to 4½ in. X 3½ in. For general purposes they are usually made with square bellows and folding tail-board, rather more substantial than those with conical bellows intended for outdoor work. There are many patterns, the principal modern improvements in field cameras being swinging front and back for focussing, or focusing table in the base-board, double and sometimes triple extension movements from the back and front for long or short focus lenses, and the use of aluminium for some of the metal-work. They are fitted with a focusing screen and geared for use on a tripod stand, though some of the smaller sizes of the modern light hand or stand cameras can be used as hand cameras with finders. The plates are carried in the usual dark-slides, but the smaller sizes of plate, from half-plate downwards, can be fitted with roll-holders for flexible films, or with film packs or other daylight changing arrangements.

Folding and Hand Cameras—Folding cameras form a class of modern portable cameras which have many advantages in their use for outdoor or indoor work and when portable apparatus is necessary, or stand work from quarter-plate to 7 in. X 5 in. They may have all the parts of a stand camera and be made to take glass plates, flat or roll films, but have the advantage of forming a convenient package enclosing camera, lens, and shutter, in position for immediate use when opened out (Fig. 2). Most of them are fitted with a ground glass and finders, and may focus by scale in the same way as hand cameras. With an apparatus of this kind on a light stand any class of outdoor work can be undertaken within the size of the plate, and the extension of the bellows, which should be quite double the focus of the lens.

The multiplicity of forms and arrangements of hand cameras makes it difficult to classify them into distinct types; but they may be mainly divided into box and folding cameras, and further into (a) cameras with enclosed changing magazines for plates or flat films; (b) with enclosed roll film on spools; (c) with separate changing magazines, changing boxes or roll-holders; (d) with single, double or multiple plate carriers or film-packs. Most cameras that will take glass plates in the ordinary plate-holders will take cut films in suitable sheaths or can be fitted with envelope slides, film-packs or roll-holders. The normal size for half-plate cameras is the double plate (4½ in. X 3½ in.); or the continental size 9 X 12 cm.; 5 in. X 4 in. is also a popular size, and cameras for the post-card size, 5½ in. X 3½ in. or 15 X 10 cm. have been largely adopted. Smaller sizes are made for lantern plates and for the lightest export cameras, in the form of stereoscopes, field-glasses or watches, as in the "Ticka," but the pictures are small and require enlarging. Hand cameras are constructed on the same principles as stand cameras, but, being specially intended for instantaneous work, they are simplified and adapted for rapid focusing and exposure. The focusing screen is superseded or supplemented by finders arranged to show the limits of the subject on the plate, the focusing being adjusted by the infinity catches and focusing scales above noticed. Swing-backs and fronts are often dispensed with, but are desirable adjuncts, and a rising and falling front particularly so. Lenses of fairly long focus, aperture-piercing power, preferably of the anastigmatic type, or a rapid aplanat, should be used, but for very rapid work anastigmats working from f/4 to f/6 will be more convenient. Hand cameras can also be fitted with telephoto objectives of large aperture. Some cheap hand cameras are fitted with single landscape lenses or aplanats working about f/11 or lower, but the want of intensity limits their use to well-illuminated subjects. They are nowadays much used in hand cameras, and for ordinary purposes should give fairly accurate exposures from ½ to 2½ of a second or less and also time exposures. Some central shutters are speeded for shorter exposures to ½ to 4⁄10 of a second, but for those focal plane shutters is the suitable, and for the more rapid exposures to ½ to 1⁄10 of a second and less are necessary. The shutter should be efficient, regular in action, and regulated by gentle pressure, pneumatic or otherwise. Mechanism for assisting the shutter, by hand or by weight, should be replaceable by others. The arrangement is simple and effective, but the bag, usually made of soft leather or cloth, is liable to wear and puncture, and may make dust. The cameras with double magazines in which unexposed plates are recorded automatically, and duplicate exposures prevented as far as practicable. A circular level placed near the finder is useful.

The choice of a hand camera depends upon the circumstances in which it is to be used, and the purpose for which it is principally required. For general work and with the modern facilities for copying, a single or double plate camera is preferable, and exposed rapidly in succession, are convenient, but their use is limited and they are liable to get out of order.

A third class are the reflex and other hand cameras with focal plane shutters for quickly taking rapid instantaneous work as noticed below. There are two types of light folding hand or stand cameras, specially adapted for hand camera work—those plates are being shot on roll films, and the folding pocket Kodak or other roll-film cameras. The former are made of very light construction with mahogany or metal bodies, wooden or aluminium base-plates, thin metal dark-slides (Fig. 3). The cameras of the pocket Kodak type of similar construction are also made to take roll films on spools, or with an attachment for focusing glass and dark-slides for taking plates and cut films. Attached to a slang-strap the quarter-plate size can be conveniently carried in a side-pocket. Watson's "Defl" folding camera is fitted with a focal plane shutter (Fig. 4). The "Selfix carbine" camera has a self-erecting front bringing the lens at once into position for use on opening out. Those fitted with large aperture, fairly large aperture, double extension, and rising and falling fronts are of the single type, and those without the advantage of a rising and falling front are of the single type, and those without the advantage of a rising and falling front are of the single type, and those without the advantage of a rising and falling front. Of box or magazine cameras there is an immense variety. In some the lens is fixed for all objects within a certain distance, in others it is adjusted by a focusing scale on the lens or by an extending front. In the "Eureka" or "Yale," is the "bag," in which a supply of plates or films in sheaths, is kept in a magazine behind the camera, ready for exposure. It is exposed while being lifted with the fingers into a bag or expanding chamber above the magazine and placed behind the rest of the plates at the back, a fresh plate taking its place in front. In some forms the magazine are removable by hand and replaced by others. The arrangement is simple and effective, but the bag, usually made of soft leather or cloth, is liable to wear and puncture, and may make dust. The cameras with double magazines in which unexposed plates are recorded automatically, and duplicate exposures prevented as far as practicable. A circular level placed near the finder is useful.

The choice of a hand camera depends upon the circumstances in which it is to be used, and the purpose for which it is principally required. For general work and with the modern facilities for copying, a single or double plate camera is preferable, and exposed rapidly in succession, are convenient, but their use is limited and they are liable to get out of order.

A third class are the reflex and other hand cameras with focal plane shutters for quickly taking rapid instantaneous work as noticed below. There are two types of light folding hand or stand cameras, specially adapted for hand camera work—those plates are being shot on roll films, and the folding pocket Kodak or other roll-film cameras. The former are made of very light construction with mahogany or metal bodies, wooden or aluminium base-plates, thin metal dark-slides (Fig. 3). The cameras of the pocket Kodak type of similar construction are also made to take roll films on spools, or with an attachment for focusing glass and dark-slides for taking plates and cut films. Attached to a slang-strap the quarter-plate size can be conveniently carried in a side-pocket. Watson's "Defl" folding camera is fitted with a focal plane shutter (Fig. 4). The "Selfix carbine" camera has a self-erecting front bringing the lens at once into position for use on opening out. Those fitted with large aperture, fairly large aperture, double extension, and rising and falling fronts are of the single type, and those without the advantage of a rising and falling front are of the single type, and those without the advantage of a rising and falling front. Of box or magazine cameras there is an immense variety. In some the lens is fixed for all objects within a certain distance, in others it is adjusted by a focusing scale on the lens or by an extending front. In the "Eureka" or "Yale," is the "bag," in
ingenious devices have been invented for effecting the change (fig. 5). Some forms are effective and popular on account of their compactness and readiness for immediate exposure, but there is always a risk of the mechanism failing, and care has to be taken in charging them to lay the plates truly in their places. The very handy, binocular cameras, or photo-jumelles, of which the Verascope* (fig. 6) is a type, are of this class, and have additional

Fig. 7.—Beck's Dai-Cornex Daylight-loading Camera.

magazines. So also are hand cameras of R. and J. Beck's "Frena" type, specially constructed for using still-celluloid films. The films are notched on two sides and packed in bundles alternately with cards similarly notched. The pack of films and cards is placed in a magazine at the back of the camera, and by the movement of a lever after exposure, the exposed film and its following card are released, and by turning this lever a second receptacle. A "folding Frena" is now made as a folding camera with attached magazine for films, without which it can be used separately for plates. R. and J. Beck's new "Frena" is a great improvement in this form of camera, being a daylight-loading box magazine camera for plates, the plates being packed in a bundle of ridged sheaths, so that they are quite protected from light and dirt. In other respects it resembles other magazine cameras (fig. 7). Another useful magazine camera is the "Zambex," carrying either plates or films, held in skeleton frames in envelopes which can be loaded for ready use in the back of the camera and exposed consecutively. For work in which speed is of primary importance hand cameras fitted with very rapid lenses and focal plane shutters are necessary, and several forms of portable collapsible cameras of this kind are now available, such as the Goerz-Anschütz, Zeiss's "Palmo," Watson's "Vril" (fig. 8), Adams's "Idento," &c., and are lighter and more portable than the reflex cameras. Hand cameras are generally fitted with screw-bushes for mounting on a tripod stand when time exposures are wanted. The light folding wooden tripod stands noted below are specially suitable.

Twin-lens and Reflex Cameras.—For photographing animals, objects in motion, etc., it is important to have the means of watching the movement till the critical moment of exposure arrives. For this a camera fitted with two lenses working in two separate compartments (fig. 9) or more simply with a mirror throwing a full-sized unreversed image of the object from the lens on to the focusing screen (fig. 10). With the former, which has the advantage that the image is seen before and after exposure, the lenses must be of exactly equal focus and focused together by the same motion of the rack-work, the object being viewed on the focusing screen of the upper compartment, and the plate kept ready for the lower to be exposed when desired. Binocular hand cameras are also made on this principle, one compartment serving for focusing, the other holding lens and plate. The stereoscopic cameras are another form of twin-lens cameras, and are usually made for also taking single panoramic pictures.

In reflex cameras only one lens is necessary, though two are convenient, and can be used somewhat as in fig. 9. They generally consist of a cubical box camera containing a movable mirror facing the lens at an angle of 45° and throwing up the image projected from it on to a horizontal focusing screen, on which it is viewed through a flexible hood which folds down in the upper part of the camera when not in use (fig. 10). In order to get the greatest rapidity of exposure a focal-plane shutter is generally fitted, and by a single movement of the release the mirror is smoothly lifted and the plate exposed simultaneously. They should be fitted with anastigmatic lenses working at large apertures for very rapid work. In some forms the lens is fixed, but usually there is a front yellow extension for long-focus lenses, with rising and falling front, to which swing motion may be given, a swing-back not being generally used with the focal plane shutter. In the "Ermex" camera E. Human has made an arrangement by which the camera back, horizontal viewing screen and reflector are made to swing simultaneously, by a rack and pinion movement. They may also have reversing or revolving backs for quickly changing the position of the plate. 5 in. X 4 in. and 3 in. X 4 in. are the usual sizes of the plates, but larger and smaller sizes are also available. These cameras require the best workmanship and perfect mechanism for successful working and freedom from any jarring movement in releasing the shutter or acting the focusing screen for accurate register with the focus of the lens on the plate. Those forms in which the image can also be viewed at the height of the eye, as in the Graflex (fig. 10), are preferred. Although reflex cameras are rather heavy and bulky as hand cameras, they have many advantages over the ordinary hand camera with finder and focusing scales for the purpose of the press photographer, the naturalist and others, in observing and recording very rapid movements, and have come into very general use for such purposes. They permit the accurate focusing of a full-sized image on the ground-glass up to the moment of exposure, especially useful when lenses of long or short focus are required and when the rising or swing front is in use. The aspect of this image on the ground-glass is also a great aid in the selection and placing of the subject and in judging the exposure required for it. They practically have all the advantages of a stand camera and can be used as such on a stand for subjects requiring prolonged exposure. They are also coming into increasing use in studio work for portraits of children, &c., and their use and adjustments are discussed by G. E. Brown in the British Journal Almanac for 1909.

Panoramic Cameras.—Many so-called "panoramic cameras have been introduced from time to time, among them T. Sutton's (1861), and J. R. Johnson's "Pantascopic" (1864), but did not

PHOTOGRAPHY

The apparatus falls pictures taken in the field as well as from hand held cameras, and is carried in a view meter. The illumination of the image is regulated by an adjustable vertical slit in a tube attached to the lens inside the box, and by altering the rate at which the film is wound up the film is rewound on a spool. Some variations of this method have been proposed, in which reflecting prisms replace the mirrors. The different systems have been discussed by W. Gamble (Ph. Jour. 1903, 24, 107), the latter also by L. Bridges and L. Butler in Proc. Soc. Phot. Engrs. 1901, 34, 107. It embraces the three colour cameras for landscape work in Ph. Jour. 1904, 34, 181, and 1908, xxiv. 331.

Enduring Camera.—These cameras vary in form, according to the size and type of the illumination, but ordinarily consist of a portable or tripod extension bellows camera, with a holder for the negative or transparency at one end, and for the sensitive plate or paper the other end. The lens is being replaced on a fixed tripod between the two. Some recent forms of "daylight enlargers" can be used for making an ordinary camera. Other cheaper ones are on the fixed-focus principle. Enlargers for use with artificial light are made like a special camera, with a separate lens and fixed paper or film, or fitted to a sensitive plate or paper fixed on an easel or screen. A simple arrangement for daylight enlarging is to fix a suitable camera on to a larger one by a sliding front, and mount the two on a studio stand, using the former than the latter. Several such enlargers are on the market. The special apparatus is required for developing and fixing the exposed films. They are wound on large rollers supported over troughs filled with the necessities (the need of a Kine-magraphe). The mechanical arrangements are treated in H. V. Hopwood, Lighting Pictures (1899); F. P. Liesegang, Handbuch der praktischen Kine-magraphe (1907); K. W. Wolf-Czapek, Die Kine-magraphe (1909); and Lindsay Johnson, Photographic Optics (1909); Eder's Jahrbuecher.

A method of cinematography in colour was introduced by G. A. Smith and C. Urban in 1908, the main features of it being the use of a double exposure, with the negatives opposed to each other, and the imposition of the colour records by persistence of vision; the use of two-colour records instead of three, in order to reduce the interval between the successive presentations; adaptation to existing cinematograph machinery and films. These conditions are fulfilled by the use, in place of the ordinary revolving sector shutter in front of the lens passing intermittent white light, of a special, more rapidly revolving shutter divided into four sectors, one fitted with orange-red glass, another with blue-green glass, one with blue-violet glass, and one with yellow, red, and orange, scarlet to deepest red; whilst the latter passes with speed the same as the green. In addition, supplementary blue rays being added. The results are satisfactory and the method promises to be of great practical value (see Jour. Roy. Soc. Arts, 1908, 57, No. 2926).

Special cameras are made for various kinds of scientific research in photo-micrography, photo-spectroscopy, astronomical photography, &c.

Tripped Stands.—Field cameras are usually supported on wooden tripods, folding or tripod stands, the legs being fixed or separate or fixed in the base-board of the camera. The legs should be capable of extension up to about 5 ft. and adjustable in length for use on uneven ground. A tripod stand may be light but must be capable of carrying a rigid weight, say 40 lb. The use of rubber or cork may be fitted to the points of the legs, and in some cases it may be desirable to strengthen the tripod by a folding adjustable brace. W. Butler's "Swimmcam" camera stand is made to enable the camera to be securely fixed in awkward positions and is available at the special feature, great extension, swivel points to the feet, &c. For hand cameras the very light, portable metal folding and walking-stick stands are convenient.
Photographic Objectives or Lenses.

The objective is the most important item of photographic apparatus, because upon it depends the perfection with which a perfect delicate picture is projected upon the surface of the sensitive plate of objects in the different planes forming the field of view, which naturally would come to a focus on a surface of the objective required to be equally illuminated and sharply defined, within a limit of confusion from \( \frac{1}{10} \) to \( \frac{1}{20} \) of an inch, over a sufficiently wide angle. A good objective must also pass sufficient light to produce the required effect. The optical powers of objectives differ; the chemical and visual fact must coincide exactly, and it must not disturb straight or parallel lines. The fulfilment of these conditions is complicated by the presence of sundry focal displacements or aberrations. 1. Aplanatism, which accompanies coma in single lenses, and is usually present in symmetrical aplanats, manifests itself by forming two sets of images of points off the axis, lying in two separate curved surfaces, one set focusing tangentially as more or less horizontal lines, the other radially as more or less vertical pencils of rays: illumination with light of these rays causes want of definition and difference of focus between horizontal and vertical lines away from the centre. 4. Curvature of field, also increasing with the obliquity of the rays. 5. Distortion, occurring according to the laws of perspective and accompanying the subjective. With the single meniscus view lens, used with its concave surface towards the object and a diaphragm in front, a square will appear barrel shaped from inward contraction of the lines of force, but with the convex surface turned towards the object and the diaphragm behind, it will appear with concave sides from outward expansion from the centre. It can be corrected by using two such lenses with the convex sides outwards and a central diaphragm. Periscopics and the linear forms of the orthoscopic and telephoto types generally show the lesser form of distortion. 6. Chromatic aberration, produced by the dispersion of light, which causes in the lens, and the difference of the colored rays composing it coming to a focus at different distances from the visual focus of the wave-length. It thus affects both the positions and sizes of the image for the different wave-lengths, and makes the time for which the rays of blue, green, and yellow are to be corrected, but for the process of photography in three colours, achromatic lenses, in which perfect coincidence of the coloured rays is secured, are required to obtain the accurate register of the three images. The corrections are effected by compensating lenses of different refractive powers (see ABESSION). In constructing photographic objectives these aberrations and distortions have to be neutralized, by regulating the curves of the different positive and negative component lenses, the refractive and dispersive indices of the glasses from which they are made, and the distances of the refracting surfaces, so as to give a lens object a perfect image, as possible stigmatic or focusing to a point, giving an image well defined and undistorted. This perfect correction could never be effected in objectives made before 1857, and very few could be effectively used at their full apertures, because light for lining lenses should be over, there were always residual aberrations affecting the oblique rays and necessitating the use of a diaphragm, which by lengthening out the rays caused them to define clearly, their inherent intensity and rapidity of working. The introduction of rapid gelatin dry plates enabled photographs to be taken with a greater rapidity than before, and led to a demand for greater intensity and speed of work. 1. Single achromatic combinations. 2. Unsymmetrical doublets. 3. Symmetrical doublets. 4. Triples combinations. 5. Anastigmatic combinations—symmetrical and unsymmetrical. 6. Telephotographic objectives. 7. Anachromat combinations. They are also sometimes classified according to their rapidity, as expressed by their effective apertures, into "extra rapid," with apertures larger than \( f/6 \); "rapid," with apertures from \( f/6 \) to \( f/8 \); "slow," with apertures less than \( f/11 \). Another classification is according to the angle of view, "narrow angle" up to \( 5^\circ \); medium angle up to \( 60^\circ \); "wide angle" up to \( 90^\circ \), and over, more. Many lenses are made in series, differing in rapidity and angle of view as well as in length of focus. 1. Single Achromatic Combination or Landscape Lens. This is the earliest form of photographic objective, evolved from W. H. Wollaston's improved single perisopic meniscus camera obscura lens (1812). It was later improved by L. J. M. Daguerre, though it required correction for chemical focus, as did the object glasses of telescopes or opera glasses first used for photography. The single landscape lens usually consists of a positive meniscus, focused of a biconvex positive crown cemented to a biconvex negative flint to secure achromatism and partially correct the spherical aberration, and may be taken as the type of the "old photographic achromat lens."

PHOTOGRAPHY

APPARATUS

FIG. 23.—R. Steinheil's Improved Group Antiplanet.

FIG. 24.—Ordinary Angle Group Antiplanet.

Most of the above are portrait objectives of large aperture, but unsymmetrical doublets have also been made for landscape work. J. T. Goddard's "Combination Landscape Lens" (1859) was one of the first, and was free from the use of achromatic combinations, and could be used as a convertible lens. In 1864 T. Ross improved his "Actinic Doublets," modified from the Collen lens, in three series —"small angle," J/8, angle 30° to 50°; "ordinary angle," J/14, angle 60° to 75°; and "large angle," J/16, angle 80° to 95°. These lenses were similar to the "Globe," but unsymmetrical and more rapid. The separate elements could be used alone. Some of them were fitted with a shutter near the diaphragm. They were superseded by the "Symmetrical" lenses.

3. Symmetrical Doublets.—This class includes objectives formed of two similar combinations of lenses, usually of the convergent meniscus form, with their concave surfaces inwards and a diaphragm between them; consequently they are rectilinear and practically free from marginal distortion. Until the introduction of anastigmatic doublets they were in general use for all purposes under the name of "Aplanat," "Rectilinear," "Symmetrical," "Euryscope," &c. They are still largely used and have been improved by the use of Jena glasses in their construction.

The first recorded lens of this type was Dr. J. W. Draper's combination used in 1829 for daguerreotype portraits, consisting of two double-convex lenses 4 in. diameter, with a united focus of 8 in., mounted in a tube with a diaphragm 33 in. in front. In 1841 T. Davidson made a combination of two single lenses of the same sign, forming a similar type of portrait lens, but with PETZVAL's "Rectilinear" lens nearly 14 in. in diameter, and a united focus of 10 in. These were improved on by J. Petzval in 1855, and were followed by many others in working on the "Aplanat." T. Steinheil made an unsymmetrical aplanatic portrait combination of peculiar construction, working at J/3-2. It was an improvement on his similar symmetrical "Portrait-Aplanat;"

It had six reflecting surfaces and nearly approached a triplet (fig. 21). Steinheil's "Group Aplanats" (1879), J/14, angle 70°, were an improvement on the ordinary "Aplanats," but were superseded in 1881 by the "Group Antiplanets," J/5, angle 70°, lenses of a distinct type (fig. 22). They were a further advance on the "Aplanats," working at larger apertures and giving better definition. This lens is interesting as the first in which astigmatism was eliminated by combining a "crown-shaped" lens of high refractivity, with a "flint-shaped" lower lens, though the old discovery of the "Globe Antiplanet" (1803), J/6, angle 30°, Dr. R. Steinheil improved the "Group Antiplanet" as regards astigmatism and covering power by replacing the "Penta-quick" combination of a crown between two flints with a heavy barium crown in the front element instead of a flint (fig. 23). Voigtlander, who originally constructed the Petzval portrait lens, improved it in 1857 and 1886, and now makes two "Group Antiplanets" on the same principle, series J/3-2, angle 28°, for ordinary portraiture and projection, and series J/2-3, angle 22° (1900) for astrophotography, cinematography, &c., when intense illumination is required over a small field. Both are quite free from coma.

Fig. 19.—Portrait Lens.

Fig. 20.—Dallmeyer's Patent Portrait Lens.
improvement was effected in the construction of non-distorting objectives of wide or large aperture. It consisted of two positive cemented flint menisci, each composed of a dense flint with negative focus outside and a light flint with positive focus inside, its concave surfaces facing the center (fig. 26). This use of flint glasses alone was peculiar to non-astronomer lenses having been limited to monochrome and crown. These lenses were made in three rudiments: "Ordinary," f/6 or f/7, angle 60°; "Landscape," f/12 to f/15, angle 90°, also used in convertible sets; "Wide Angle Landscape," f/20 to f/25, angle 104°; "Wide Angle," f/32 to f/37, similar to the last, but with sharper definition. The "Aplanat" had many advantages over previous doublets and the triplet, being more rapid, perfectly symmetrical, so that there was no necessity for turning them when enlarging, and free from distortion or flare. There was no chromatic focus. Each component could be used alone for landscape work with double focus, subject to the ordinary defects of single lenses. By the use of Jena glasses in the "Universal Aplanat" (1886) the components of this lens were brought closer together, its work increased, and it was made more portable. J. H. Dallmeyer had been working in the same direction simultaneously with Steinheil, and had made for the Pantoscope similar lenses (fig. 27), 5/100, made of flint and crown, the front element being larger than the back (fig. 27). It was slow for ordinary purposes and was succeeded in 1867 by the well-known "Rapid Rectilinear," f/6, on the same principle as Steinheil's "Aplanat, but made of flint and crown (fig. 28)." Ross's "Rapid" and "Portable Symmetrical" lenses, Voigtlander's "Euryscope," and other similar lenses of British and foreign manufacture are of the same type, and still in use. They are excellent for general purposes and copying, but are unsuitable for use in cameras, for no such lenses are always present, and although they can be used with larger apertures than the triplets they displaced, they require stopping down to secure good marginal definition over the size of plate they are said to cover. By the use of Jena glasses they have been improved for work of larger apertures, and some are made with triple cemented elements.

4. Triples Combinations: Old Types.—This class comprises objectives composed of three separate cemented doublets of various forms. Each from other. An early form of this type was made by Andrew Ross (1841) for W. H. Fox Talbot, others by F. S. Archer, J. T. Goddard (1859), T. Sutton (1860), but they never came into general use. J. H. Dallmeyer's "Triplet Aplanatic Lens" (1861), f/10, angle 60°, now out of date, was an excellent non-distorting lens, and was useful for work and copying (fig. 29). As made by Dallmeyer, the inner surfaces of the front and back components were slightly concave, but in T. Ross's "Achromatic Triplet," f/1.8, 1861, both of them were flat. The centre lens was an achromatic negative serving to flatten the field.

5. Achromatic Combinations: Symmetrical and Unsymmetrical.—As already stated, it was found practically impossible to obtain flatness of field, together with freedom from astigmatism, in objectives constructed with the old optical glasses. A Steinheil attempted it in the "Anastigmat," but with only partial success. The Abbe and Schott Jena glasses, issued in 1886, put a new power into the hands of opticians by largely increasing their choice of glasses with different refractive indices. Whereas the old glasses had high refractivity with higher dispersion, in the new ones high refractivity with lower dispersion could be set against lower refractivity with higher dispersion.

Between 1886 and 1889 the first attempts to make anastigmatic objectives with the new glasses were made by M. Mittenzweil of Zwickau, F. R. G. Gray of New Jersey, F. A. Hartnack and A. Miethe of Berlin, C. B. Goerz of Vienna ("Achromat" and "Apochromat") and F. H. von Voigtlander of Brunswick, with more or less success, but progress was hindered by the instability of some of the early glasses. Progress was afterwards renewed by obtaining the soft glasses between two hard ones. In 1888 Dr. H. C. Schroeder worked out for Messrs. Ross the Concentric Lens (fig. 30), consisting of two cemented elements with a symmetrical doublet of novel construction, each element consisting of a plano-convex crown of high refractivity cemented to a plano-concave flint of lower refractivity, but about equal or higher dispersion. Both the un cemented surfaces were spherical and concentric. At f/6 it gave sharp definition and flatness of field with freedom from astigmatism, distortion there being none above an angle of 75°. It was an excellent lens, though slow, and has been superseded by the "Homocentric" and other more rapid anastigmats. Dr. Paul Rudolph, of Messrs. Carl Zeiss & Co., Jena, worked out in 1889 a new and successful method of constructing a photographic objective by which astigmatism of the oblique rays and the want of marginal definition due to it could be eliminated without loss of rapidity, so that a comparatively extended field could be covered with a large aperture. This he did on the principle of the opposite or opposed gradation of the refractive indices in the front and back lenses, by a combination of two dissimilar systems of single lenses cemented together, the positive element of each having in one case a higher and in the other a lower refractive index than that of the negative element with which it was associated. The front system, relied upon for the correction of spherical aberration, was made of the old glasses, a crown positive of low and a flint negative of high refractivity, with the back system, relied upon for the anastigmatic flattening of the field, was made of the new glasses, a crown positive of high and a flint negative of low refractivity. Both systems being spherically and chromatically corrected for a large aperture, the field was flattened, the astigmatism of the one being corrected by the opposite astigmatism of the other, without destroying the flatness of the field over a large angle (see E. Jb., 1891 and 1893; M. von Rohr's Geschichte, and A. R. Lumar, Photographic Optics, for further details). They were issued by Messrs. Zeiss and their licensees (in England, Messrs. Ross), in 1890, in two different types. The more rapid had five lenses (fig. 31), two of ordinary glasses in the front normal achromat, and three in the back abnormal achromat, two crowns of very high refractive power, with a negative flint of very low refractive power between them.

The fifth lens assisted in removing spherical aberrations of higher orders with large apertures. The second type, series IIIa, f/6.5, 1899 (fig. 32), had only two lenses, the functions of which were as above. These combinations could not be used separately as single lenses, but they are now used in a" Protar" combination, f/4, 1899; f/5.6, 1900; f/6.3, 1901; f/7, 1902. In 1894 Dr. Rudolph devoted himself to perfecting the single landscape lens, and constructed on the same principle a single combination of three lenses, the central one having a refractive index between the indices of the two others, and one of its cemented surfaces diverging, while the other was converging. At f/4.5 this lens gave an anastigmatic flat image with freedom from spherical aberration on or off the axis. It was, however, not brought out until 1893, as a convertible lens or "Satz-Anastigmat," series VI, f/4.8, and VIIa, f/7.7 (figs. 33 and 34). In the meantime Dr. E. von Hoëg (C. B. Goerz) and Dr. A. Steinheil had also been working at the problem and had independently calculated lenses similar to Rudolph's, but, whereas he had devoted himself to perfecting the single lens, they sought more perfect correction by combining two single anastigmatic lenses to form a doublet. Dr. Rudolph had the same idea, but Messrs. Goerz seized the priority of patent in 1892, and in 1893 brought out their "Double Anastigmat," now known as the "Dagor." It was the first symmetrical anastigmat which combined freedom from astigmatism with flatness of field and great covering power at the large aperture of f/7-7 (fig. 35). Both these types of Zeiss's "Protars" and Goerz's "Dagor" anastigmats have since
These lenses are designed to be free from diaphragm corrections, while the focal power of the negative lens is made as closely equal to the combined focal powers of the two positive lenses as may be necessary for the flattening of the field and correcting marginal astigmatism. They are not convertible, but arrangements are made for replacing the back lens by a low-power extension lens (Ph. Jour. 1895, 19, p. 64). Series III, f/6.5 (fig. 40), and series IV, f/5.6, are portrait lenses. In the larger objectives of series II, the back lenses are adjustable for uniform sharp definition or a soft diffusion of focus. In a later series VI (1907), f/5.6, this adjustment for diffusion is given to the front lens and is so arranged for portraiture that the diffusing adjustment and iris diaphragm can be operated from the back of the camera while viewing the focusing screen.

A special fully corrected "Process" lens on the same general principle has recently been brought out for three-colour work and fine-line reproduction. Another distinctly new type of anastigmatic objective, involving several new principles of construction was patented by H. L. Aldis in 1895, and brought out by Messrs Dallmeyer in three series, under the name of "Stigmatic" (Ph. Jour. 1896, 9, p. 17). It also approaches the triplet construction and depends on the introduction of air-spaces between the components. According to Aldis, three conditions must be observed to obtain a flat field free from marginal astigmatism: (1) The converging lenses must be of high, the diverging lens, low, refractive index; (2) the converging and diverging components must be separated by a considerable interval; (3) thick meniscus glasses should be used. The first "Stigmatic" was a portrait lens, series I, 1896, f/4. It has been extended in two forms, with a triple front lens, and a back negative system of a single thick crown lens of high refractive index with a negative cemented meniscus. In the second form (fig. 41), the front component consists of a cemented positive and negative, and both parts of the back component are cemented lenses. All the converging lenses are made from the back, but while both the diverging lenses in the back component are a light silicate crown, it is fully corrected for spherical and chromatic aberration, free from distortion and nearly so for astigmatism, giving high definition over a flat field of 60°. Diffusion of focus is obtained by unscrewing the back cell. Series II. (1897) is on the same principle but differs in construction, working at f/6 over an angle of 65° as a universal and convertible lens (fig. 42). The front or back component can be used alone, giving the choice of two focal lengths, 11 and twice the focal length of the complete lens. The principles of its construction were described by T. R. Dallmeyer in Ph. Jour. 1897, 21, p. 167. Series III, f/7.5, f/7.6 give sharp definition over a plate two sizes larger. The single components are not convertible.

In 1897 Messrs Zeiss issued the "Planar," an objective of large aperture based on the principle of the Gauss telephoto objective. It is a symmetrical doublet, each element consisting of three lenses, with the convex single lens component as a convergent lens, in which greater sharpness of definition and intensity, with perfect freedom from astigmatism and distortion in the single lens, were claimed. It was issued in 1898, but, like an earlier analogous quintuplet of Messrs Taylor & Hobson (1895), it has not come into any practical use. The cost and difficulty of construction. The latter firm, however, brought out in 1906 a new symmetrical quintuplet at f/6.8.

A triple anastigmatic construction containing remarkable new features, constructed and patented by H. D. Taylor, was issued in 1895 by Messrs Taylor, Taylor & Hobson under the name of the " Cooke Lens." and later by Messrs Voigtlander as the "Triple Anastigmatic." It consists of three single lenses, two of them positive crossed lenses of crown glass with high refraction and low dispersion, and with their most convex sides outwards, and between them, in front of the diaphragm, a single biocconcave of light flint (fig. 39). All
consists of two unsymmetrical combinations, each formed of two single lenses of very transparent glass, dense baryta crown and light flint, separated by positive and negative air-spaces (fig. 44). The separate halves cannot be used as single lenses, neither being fully corrected for colour. It is well adapted for portraiture, groups or landscapes, especially for rapid hand camera work, on account of its covering power, freedom from astigmatism and sharp definition with large relative aperture.

**Fig. 43.—Planar. Series Ia.**//6, f/4.** Fig. 44.—Zeiss’s “Unar.”**

In 1898 Messrs Goerz patented their “Double Anastigmat Color,” series II., f/4.5 to f/5. It is a symmetrical doublet, each element consisting of two single lenses: a positive high and a negative of low refractive index, separated by an air-space (fig. 45). It is derived from the triple anastigmats by decreasing the refractive power of the central convex meniscus to the refractive power of air, so that it becomes a convex air-space between a double convex and a double concave lens. Less deeply curved surfaces can be given to the lenses, and the doublet gives anastigmatic flatness of field over an angle of 62° to 66°, equal to the best anastigmats with a still larger aperture. Series Ia., f/6.3, is similar and recommended for hand cameras, the aperture being smaller. Goerz’s “ Hypergon,” (1900) f/22, angle 135°, is a symmetrical doublet, each element consisting of a negative flint meniscus of higher refraction, and a positive crown of lower refraction with an air-space between them in the form of a negative lens. The back element can be used alone. The “Lumiar Series” of Goerz-Rodenstock is similar. In 1902 Messrs Ross brought out the “Homocentric,” a symmetrical doublet, each element consisting of a negative and positive meniscus separated by an air-space (fig. 50). It is corrected so that all light passing through the object are converged again into one point in the image. It is also quite free from spherical zones, is not altered in focus with different diaphragms, and has thus exquisite definition. The colour correction is so perfect that the different coloured images are identical in size and position, thus rendering it specially suitable for three-colour and process work. The back lens can be used alone, with diaphragms, as a single lens of about double the focus of the doublet. Series II, f/4, and III, f/6, f/7, f/8, for rapid and instantaneous work; V, f/8, for ordinary purposes; VI. f/8, for process work and three-colour reproduction. A later series, IV, (1907), “ Compound Homocentric,” f/6-8, differs from the others in being a symmetrical doublet composed of two thick cemented elements, very close together and separated by a diaphragm. It is specially suited for outdoor work, also for copying and enlarging, having good covering power. Zeiss’s “Tessar” (1902) is a rapid unsymmetrical doublet, formed of two separated uncemented positive and negative lenses in the front element and a cemented meniscus in the back element (fig. 51). The two halve of the cemented doublet are anastigmatic and free from distortion. Messrs Voigtlander’s “Heliar” (1902), f/4-5, angle 90°, calculated by Dr. H. Harting, is an objective of large aperture, suitable for portraits and very rapid instantaneous work, being well corrected for astigmatism, coma and curvature of field, with freedom from flare. It is a triplet consisting of two unsymmetrical combinations, each formed of two single lenses of very transparent glass, dense baryta crown and light flint, separated by positive and negative air-spaces (fig. 44). The separate halves cannot be used as single lenses, neither being fully corrected for colour. It is well adapted for portraiture, groups or landscapes, especially for rapid hand camera work, on account of its covering power, freedom from astigmatism and sharp definition with large relative aperture.

**Fig. 45.—Goerz’s “Color.”**

**Fig. 46.—Goerz’s “Homocentric.”**

symmetrical doublet of remarkable construction, consisting of only two single semi-globular, very thin lenses, with diaphragm at the centre of curvature between them. Astigmatism and curvature have been eliminated, and definition is good over the whole angle with no distortion. Chromatic aberration is uncorrected, but compensated for by using a small stop. A star mask is fitted in front of the lens to allow for falling off of illumination towards the margin (E. Jb., 1901, p. 163). The “Syntor” (1903), Series IIa., f/6-8, angle 64° to 70°, is on the same principle as the “Color,” but cheaper, for use in hand cameras or telephoto combinations. The “Homocentric,” Series II, f/6.3, is a lens with diminished secondary spectrum, for three-colour reproductions, half-tone process work, and general purposes. It is a symmetrical doublet, each element consisting of a negative and positive separated by an air-space (fig. 46). The negative is composed of three cemented lenses, which correct the spherical and chromatic aberrations more fully than hitherto possible, so that all the colours of the spectrum are focused in the same invariable plane. It gives great crispness of definition at full aperture (W. Zschokke, E. Jb., 1904, p. 165). Goerz’s “Pantar,” f/6-3 (1904), is a convertible 4-lens anastigmat, and an improvement on the “Dagor,” in that the single elements are completely corrected for coma, and thus form efficient long-focus lenses for landscape, &c., at an aperture of f/12-5, while the doublet formed by various combinations of the single elements are universal objectives working from f/6-3 to f/7. The single elements are similar to those of the “Dagor,” but have an additional negative convex back lens. It is a long-focus objective with short back focus, and is made in two forms, Series II., f/6 (fig. 47), and series III. (fig. 48). In the latter the back element is a doublet, and the front combination of infinite focal length. By discarding the symmetrical form simplicity is secured, while open or reflecting surfaces are avoided. Special attention has been paid to perfect correction of spherical aberration in the centre of the field, with lighter, smaller and cheaper than series II. The “ Duo” lens of the same maker (1907) is intended to replace the front lens and double the focus, but with less rapidity and with any loss of quality. The “Trio” (1908) is similar, but only increases the focus one and a half times and is thus more suitable for cameras of short extension. The Alidis “Oys” anastigmat, series II, f/5-5, angle 85°, is an improved form. Being an unsymmetrical compound doublet it is free from the defects incident to air-spaces and is constructed to give more perfect correction for flatness of field with large aperture and wide angle.

It is generally stated that it is impossible to make a spherically, chromatically and anastigmatically corrected photographic objective with the old optical glasses. K. Martin, of Messrs Busch of Rathenow, has, however, shown (E. Jb., 1902, p. 68) that it is quite possible to do so with a system of separated lenses, and that it is immaterial whether the index of the flint or the crown is the higher. An anastigmat on this principle was issued by Messrs Busch in 1902, as the “Omnar,” series III, f/7 (fig. 49). Series II, f/5-5, angle 75°, and I, f/4.5, have since been issued. It is a symmetrical doublet, each element consisting of a negative flint meniscus of higher refraction, and a positive crown of lower refraction with an air-space between them in the form of a negative lens. The back element can be used alone. The “Lumiar” Series of Goerz-Rodenstock is similar. In 1902 Messrs Ross brought out the “Homocentric,” a symmetrical doublet, each element consisting of a negative and positive meniscus separated by an air-space (fig. 50). It is corrected so that all light passing through the object are converged again into one point in the image. It is also quite free from spherical zones, is not altered in focus with different diaphragms, and has thus exquisite definition. The colour correction is so perfect that the different coloured images are identical in size and position, thus rendering it specially suitable for three-colour and process work. The back lens can be used alone, with diaphragms, as a single lens of about double the focus of the doublet. Series II, f/6-8, and III, f/6-3, for rapid and instantaneous work; V, f/8, for ordinary purposes; VI, f/8, for process work and three-colour reproduction. A later series, IV, (1907), “Compound Homocentric,” f/6-8, differs from the others in being a symmetrical doublet composed of two thick cemented elements, very close together and separated by a diaphragm. It is specially suited for outdoor work, also for copying and enlarging, having good covering power. Zeiss’s “Tessar” (1902) is a rapid unsymmetrical doublet, formed of two separated uncemented positive and negative lenses in the front element and a cemented meniscus in the back element (fig. 51). The two halve of the cemented doublet are anastigmatic and free from distortion. Messrs Voigtlander’s “Heliar” (1902), f/4-5, angle 90°, calculated by Dr. H. Harting, is an objective of large aperture, suitable for portraits and very rapid instantaneous work, being well corrected for astigmatism, coma and curvature of field, with freedom from flare. It is a triplet consisting of two unsymmetrical combinations, each formed of two single lenses of very transparent glass, dense baryta crown and light flint, separated by positive and negative air-spaces (fig. 44). The separate halves cannot be used as single lenses, neither being fully corrected for colour. It is well adapted for portraiture, groups or landscapes, especially for rapid hand camera work, on account of its covering power, freedom from astigmatism and sharp definition with large relative aperture.
of a central negative lens, with cemented double front and back lenses (fig. 52). The negative lenses are of light silicate flint, the two positive of the heavier crown and flint glass. Besides being a rapid and universal lens, it is specially suitable for half-tone process work, with a large diaphragm (E. Jb., 1903, p. 117). The "Dynar" (1903), f/6, angle 60°, is of somewhat similar construction, but differs from the "Heliar" in the positive lenses of the cemented pairs being outside instead of towards the central lens. It can only be used as a whole. It is made of hard coloured Jena glasses, giving very brilliancy and uniformity of illumination over a large angle, and is especially adapted for very rapid hand-camera work.

Dr. R. Steinheil's "Unofocal" (1903), f/4.5 is a symmetrical doublet, each element consisting of two single separated lenses of equal refractive power and of equal focus of opposite signs, hence its name. Each half can be used as a single lens with small stops. In its construction a quite new principle was followed, the separation of the lenses fulfilling an important part in the colour correction; explained by Conrad in Ph. Journ. (1904), p. 177. This plan satisfies the Petzval condition and removes its restrictions, so that a lens of f/4.5 can be produced with telescopic central definition, perfect freedom from distortion and flares in a flat field of 60°, with great equality of illumination (fig. 53). They are made by Messrs. Beck in two series: I., f/4.5, for portraiture, rapid hand-camera work, telephotography and projection; and II., f/6, in which the lenses are closer together, for cine-camera work and general purposes. E. Arbeit's "Euryplan" anastigmats (1903), made by Schulze Bros., Potsdam, are achromatic objectives of quite new construction, giving perfect definition with large apertures over a wide angle, made in four series: I., f/4.5, angle 80°; II., f/5.6, angle 90°; III., f/6/8 to 7.5, angle 82°; IV., f/6, 8.5. They are symmetrical doublets, each element consisting of three lenses, a new achromat formed of a crown of very high refractivity and low dispersion, separated by an air-space from a positive meniscus of the same baryta crown, with its concave side towards the diaphragm. In series I., f/4.5, the two negative are placed inside (fig. 54), in series II. and III., they are inside. The single elements are fully corrected astigmatically and chromatically, and can be used singly at double the focus (E. Jb. 1904, p. 55).

Beck's "Iso-stigmat," is a new anastigmat working in a complete objective, showing a distinct departure from the ordinary principles of construction, in that it does not fulfil the Petzval condition that the sum of the focal powers of its individual lenses multiplied by the reciprocals of their respective refractive indices should be equal to zero, or 2(f/μd) = 0. It is a 5-lens combination, two separated thin single lenses in the front element and three in the back (fig. 55). In departing from the Petzval condition very low power lenses can be used, thus reducing the initial errors to be corrected; no individual component having a shorter focal length than one in a complete objective. A special feature is the excellent correction of the oblique spherical aberrations and central aberrations, giving a practically flat field without astigmatism over angles from 60° to 90°. The half combinations can also be used alone with diaphragms as long focal lengths of considerable usefulness (A. Jb., 1902, p. 191). It is issued in six series: I. (1908), f/4.5, large aperture, for reflex press work and portraiture; IIa., f/6.5, angle 60° to 85°.

Dr. R. Steinheil's Iso-stigmat, f/4.5 is of somewhat similar, but differs from the "Heliar" in the positive lenses of the cemented pairs being outside instead of towards the central lens. It can only be used as a whole. It is made of hard coloured Jena glasses, giving very brilliancy and uniformity of illumination over a large angle, and is especially adapted for very rapid hand-camera work. Dr. R. Steinheil's "Unofocal" (1903), f/4.5 is a symmetrical doublet, each element consisting of two single separated lenses of equal refractive power and of equal focus of opposite signs, hence its name. Each half can be used as a single lens with small stops. In its construction a quite new principle was followed, the separation of the lenses fulfilling an important part in the colour correction; explained by Conrad in Ph. Journ. (1904), p. 177. This plan satisfies the Petzval condition and removes its restrictions, so that a lens of f/4.5 can be produced with telescopic central definition, perfect freedom from distortion and flares in a flat field of 60°, with great equality of illumination (fig. 53). They are made by Messrs. Beck in two series: I., f/4.5, for portraiture, rapid hand-camera work, telephotography and projection; and II., f/6, in which the lenses are closer together, for cine-camera work and general purposes. E. Arbeit's "Euryplan" anastigmats (1903), made by Schulze Bros., Potsdam, are achromatic objectives of quite new construction, giving perfect definition with large apertures over a wide angle, made in four series: I., f/4.5, angle 80°; II., f/5.6, angle 90°; III., f/6/8 to 7.5, angle 82°; IV., f/6, 8.5. They are symmetrical doublets, each element consisting of three lenses, a new achromat formed of a crown of very high refractivity and low dispersion, separated by an air-space from a positive meniscus of the same baryta crown, with its concave side towards the diaphragm. In series I., f/4.5, the two negative are placed inside (fig. 54), in series II. and III., they are inside. The single elements are fully corrected astigmatically and chromatically, and can be used singly at double the focus (E. Jb. 1904, p. 55).

Beck's "Iso-stigmat," is a new anastigmat working in a complete objective, showing a distinct departure from the ordinary principles of construction, in that it does not fulfil the Petzval condition that the sum of the focal powers of its individual lenses multiplied by the reciprocals of their respective refractive indices should be equal to zero, or 2(f/μd) = 0. It is a 5-lens combination, two separated thin single lenses in the front element and three in the back (fig. 55). In departing from the Petzval condition very low power lenses can be used, thus reducing the initial errors to be corrected; no individual component having a shorter focal length than one in a complete objective. A special feature is the excellent correction of the oblique spherical aberrations and central aberrations, giving a practically flat field without astigmatism over angles from 60° to 90°. The half combinations can also be used alone with diaphragms as long focal lengths of considerable usefulness (A. Jb., 1902, p. 191). It is issued in six series: I. (1908), f/4.5, large aperture, for reflex press work and portraiture; IIa., f/6.5, angle 60° to 85°. Having such a large reserve of covering power the latter is very useful when an extended use of the rising front is required, as, for instance, in working at a very high angle. V. (1908), f/5, "Process" lenses specially corrected to give a flat field for copying. They can be fitted with suitable reversing prisms. VI. (1908), f/5.6, variable portrait lenses, adjustable for sharp or soft definition from the back of the camera while focusing.

The above represent the principal types of anastigmats, but many more objectives of the kind, triple or quadruple, cemented or un cemented, with air-spaces, in many modifications, have been issued by English and foreign makers.

6. Telephotographic Objectives.—For some years past special objectives, or attachments, have been constructed for photographing near or distant objects, or on a magnified scale with an ordinary camera, the extension required being very much less than would be needed to obtain an image of the same size with an ordinary long-focus lens without enlargement. They consist of a combination of a positive converging with a negative diverging lens, by which the image is picked up and enlarged to varying degrees, according to the magnifications used and the extension given to the camera, thus producing the same effect as a positive lens of very much longer focus. Enlarged images of this kind can also be made by 1 combination of 2 converging lenses, one of them forming an image of the object, which is received on the other of shorter focus and projected on the sensitive plate, being enlarged or less according to the optical conditions and finite lenses, suitably adjusted. The telephotographs at Greenwich and other solar observatories, designed by Warren de la Rue, are on this principle. Portable apparatus of the kind was made in 1869 by MM. Bon and de Tournemire, and later by Jarret, but this apparatus required a greater extension of the camera, entailing more loss of intensity of the image, and has never come into use.

A simple telephotographic combination is generally employed upon as an application of the principle of the "Barlow" lens, but it really goes back to the Galilean telescope (c. 1610). J. B. Porta mentions the combination of concave and convex lenses for giving enlarged and clearer images of very distant objects (Magiae Naturalis, lib. 17, cap. 10, 1689). J. Kepler showed that by a combination of a convex with a concave lens images of objects could be depicted on paper of a larger size than by the convex lens alone, which was the principle of the camera obscura, and the camera lucida. The apparatus was made use of the same principle in his "Helioscope" for solar observations (Rosa Ursina, cap. viii. 1630). F. M. Deschales and P. Z. Traber also dealt with the question, and in J. Zahn's Oeuvres artificielles, published in 1664, there is mentioned a combination of a convex and a concave lens, with a compound enlarging lens on this principle. In his Nova Dioptrica (1692), W. Molyneux has given some interesting problems for calculating the position of the compound focus of a convex with a concave lens, with the angles subtended by an object on the focal plane. If for the simple uncorrected glasses then used we substitute a system of photographically corrected positive and negative lenses, suitably adjusted, and put a sensitive plate in place of the paper, we have the modern telephotographic apparatus. I. Porro seems to have been the first to use a combination of this kind for photographing an eclipse in 1856, and later for terrestrial objects. It consisted of an achromatic single lens combined with a concave lens. Many attempts were afterwards made in France, and also in England, to utilize the principle, but special lenses for the purpose were not available. Dr. Steinheil constructed one in 1886 for the Brussels Observatory, and another in 1890 for the Marine Department in Berlin. In 1891, curiously enough, three such combinations were worked out quite independently and patented, by T. R. Dallmeyer in London, A. Milet in Berlin and C. L. F. Regnault in Paris. These have been greatly improved by increase in the working apertures and reduction in size and weight, so that they can be used in hand cameras. They are exceedingly valuable for obtaining details of inaccessible objects at a distance, whether architectural or topographical, and for photographing animals without approaching them too closely. Large portraits can also be taken with much better effect and with a greater advantage than by using long-focus lenses much nearer to the sitter. With the very perfect telephoto-
with those of ordinary intensity the exposures are not unduly prolonged, and good definition can be obtained over an extended field.

The optical principle on which these combinations are based is very simple, and will be understood from fig. 56. It depends mainly on the fact that rays can be thrown on the screen of an object AB, the rays proceeding from it, which pass through the positive system L₁, must come to a focus at a point f₁ beyond the secondary focus f₂ of the negative system L₂, forming a virtual image. When the rays are left to continue their path they will form a virtual image, which will be more or less convergent, so that instead of coming to a focus at f₁ they will continue to converge till they reach the screen at f₂, and will there form a proportionally larger image a'b' of AB than the image a'b given by the positive lens alone at f₁; just as stated in Kepler's first law. Moreover, this image a'b' will be of the same size as if it had been produced directly by a positive lens L₁ with a focal length equal to f₂, and this distance is the equivalent focal length of the entire system. It can be found from the formula f₁ = f₂, where f₁ and f₂ are the focal lengths of L₁ and L₂ respectively, and d = f₁ + f₂ - s, being the distance between the lenses. In many instruments of the kind a scale showing the value of d is engraved on the mount. If the rays from AB come to a focus in front of L₂, on it, or beyond f₂, no real image can be projected on the screen. There is therefore a certain limit, which is greater in proportion to the length of focus of the negative system, within which the formation of a positive image is possible.

If the system is adapted as a reflecting camera, the image can be magnified by the virtual image formed by the first lens system, and the magnification will be the same as if it had been formed directly by a positive lens L₁ with a focal length equal to f₂. In the telephoto system the image is formed as a post-contrast, uniform image in the manner of the telescopes, and can be moved by the laws shown in fig. 56. The image is being magnified by the first system, and the magnification is determined by the ratio of the focal lengths of both systems.

APPARATUS [PHOTOGRAPHY]

The telephoto system consists of two separate systems of lenses, one acting as a projecting lens for the lantern, and the other forming a virtual image of the object. The magnification is determined by the ratio of the focal lengths of both systems.

7. Anachromat Lenses.—For large portraits a certain amount of spherical and chromatic aberration is unavoidable, but these effects can be reduced by using special lenses. These lenses are known as anachromat lenses. They are designed to correct for both spherical and chromatic aberration. A typical anachromat lens is shown in fig. 57. It consists of a double convex lens with a short focal length, and a concave meniscus lens, which is negative. The combination of these two lenses results in a lens that is free from both spherical and chromatic aberration.

8. The Anachromat.—The anachromat is a lens designed to correct for both spherical and chromatic aberration. It consists of two elements, one positive and one negative. The positive element is a convex lens, and the negative element is a concave lens. The combination of these two lenses results in a lens that is free from both spherical and chromatic aberration. The anachromat is useful for portrait photography, where correction for these aberrations is essential.

Fig. 57.—T. R. Dallmeyer's Compound Telephotographic Lens.

Fig. 58.—Bis-Telar.
The Royal Photographic Society in 1881 drew up some rules, which were revised in 1891 and again in 1897. For the former three there were the following:

1. As the unit for the measurement of the aperture of a lens is the diameter of the diaphragm, the term aperture is used for it, and the former unit of length will be the inch.

2. The effective aperture of a lens is that diameter of the diaphragm in relation to the focal length of a lens. The effective aperture of the lens is determined as follows: The lens must be focused for parallel rays. An opaque screen is then placed in the plane of the image at a distance from the lens equal to the focal length of the lens, and a pinhole is placed immediately behind the pinhole, when the diameter of the beam emerging from the front surface of the lens may be measured. The focus will be determined with the central plane of the plate (in the axis of the lens); an illuminant is placed immediately behind the pinhole, and the diameter of the diaphragm itself is determined in the axis of the lens. Every diaphragm is to be marked with its true aperture ratio as defined above, and the effective aperture ratio of each diaphragm is calculated, the exposure required by the preceding one. In other cases aperture may be determined by a method of uniform exposure, the highest intensity, e.g., a lens of f/6.3 would be marked for f/6.3, f/8, &c. The corresponding numbers are known as f numbers, but are only applicable for a lens focused for distance. Larger systems of photography are in use, but the above is generally adopted (see Fabre, T.E.P. Suppl. C. 38). Special diaphragms are in use for process work with ruled screens (see N.S. Amstutz, Handbook of Photography, 1907). Standards for the form and construction of cameras for attachment to the stand or for fixing movable parts, have also been laid down (Ph. Journ. 1901, 25, p. 322).

Instantaneous Shutters.

The general use of rapid dry plates and hand cameras has rendered it necessary to have some mechanical means of regulating exposures and preventing excessive enlargements of the objects. Photographers have used the principle of rapid motion, and this instantaneous shutter has become an essential part of modern photographic equipment in many forms and patterns, but practically three types are preferred—the between-lens shutter, the roller-blind shutter, and the focal plane shutter, in front of and close to the plate and forming part of the back of the camera. The universal rapidity of the two former is nominally about 1/1000 th second, that of the last about 1/10000 th second; the last being required, while with the latter speeds of 1/2000 th to 1/5000 th of a second may be attained.

Two important factors in the use of lenses are the rapidity or time in which the aperture can be opened and closed, and the efficiency, measured by the ratio of the time during which the shutter is fully open and the time occupied in opening and closing. Both factors are more or less variable, either with differences of construction, of diaphragm opening or of position of the shutter with regard to the plate and lens. In any case the efficient exposure is always less than the actual, and may be considerably so.

The time required of a shutter in photographing moving objects is regulated by the minimum time necessary to produce a well-exposed image upon the plate, with a loss of definition, or blurring, by displacement not exceeding 1/500 th second, and is therefore measured by 1/500 th second. This will depend on the state of the light and the illumination of the subject, the relative intensity of the lens as measured by its effective aperture and focal length, the sensitiveness of the plate, and the amount of effective light passing through the shutter during the exposure. The amount of displacement to be regarded against depends upon the rate of movement of the object, the direction in which it is moving with reference to the axis of the lens, its distance from the plate, and the focal length of the lens. It will be proportionately less as the distance of the object increases, and as the rate of its motion and the focal length of the lens for a given distance decrease, and will increase in the reverse order with angles to the axis of the lens, and least when the motion is directly towards it; but in that case there will be some increase in the apparent size of the object as it approaches the camera. For example: An object moving 1 m. an hour advances 17 1/2 in. per second. With a lens of 5 in. focus this would represent a displacement on the ground glass, for an object 50 ft. away, amounting to 146 in. per second. An object moving 10 m. an hour also advances 17 1/2 in. per second. With a lens of 5 in. focus this would represent a displacement on the ground glass, for an object 50 ft. away, amounting to 1460 in. per second. The exposure required by exposure may be increased in the same proportion, so that the object moving 10 m. an hour at 500 ft. distance would only require the original exposures of 3/4 to 3/2 of a second. On the other hand, this object moving 10 m. an hour at 10 ft. of the lens would be between 3/4 and 1/2 of a second. This is entirely independent of the sensitiveness of the plate, and only represents the maximum duration of exposure permissible in order to reduce the blurs of the imitate whole, with the extinction of the sensitiveness of the plate, and the intensity and amount of light acting upon it through the lens and shutter, must be adjusted so as to produce the desired photographic effect within that time. With a lens of 8 in. focal length the displacement would have increased in the first instance to 23 in. per second, and the maximum displacement required of that object, as well as that of all others, is 30 in. per second. This shows that there is an advantage in using short-focus lenses for very rapid exposures. In practice, most work of this kind is done upon quarter-plates (4 1/2 x 3 1/2 in.) with lenses of 4 1/2 to 5 in. focus. As the effect of this may be seen with a hand-camera. In this case the exposure of the plate will be exposed across the axis of the lens, an exposure sufficient for this case will be suitable for any other. Sir William Abney has discussed this question practically in his Instantaneous Photography, and it is well worthy of consideration, whether a Hand Camera, in which will be found formulae and tables for ascertaining the distances and limiting exposures for moving objects, allowing for a blur of 1/10 of an inch. In foreign treatises the limit is calculated for a displacement of 1/15 of a millimetre, or about 1/40 of an inch.

An efficient shutter should fulfill the following conditions: It should not inconvenience, be liable to get out of order, capable of being set without admitting light into the camera; easily released with a slight pressure of the finger, if a pneumatic release is not fitted, and free from any tendency to shake the camera on release. It should open and close quickly, allowing the largest possible proportion of the exposure to be made with the full aperture, and it must be capable of being repeated with tolerable certainty. Shutters should also be adaptable for use with different lenses. Three methods of varying the speed of a shutter in use are: (1) by altering the length of the slot; (2) by the retarding action of a pneumatic brake; (3) by the action of a weight, as described by W. B. Coventry as far the best. They are usually released by the pressure of the finger on the end of a lever holding the moving part in a state of tension; or, better, by J. Cadet's system of pneumatic release, or by a system of a cylinder-shutter, which may drive a piston acting on the lever holding the shutter, or open a collapsible bulb at the other end of the tube and thus exert the necessary pressure on the lever. With W. Watson's "Antinous" release a flexible wire acts directly on the piston or trigger release of a cylinder shutter. It is also adapted for roller-blind, focal plane, flaps, and various forms of between-lens shutters. It is durable, effective and convenient (see fig. 3). In many of these methods of operation the operator may be as desired, or as in the case of pneumatic release be pressing on account of its convenience and freedom from liability to shake the camera.

The following are the principal types of instantaneous shutter: (1) Flap, (2) drop, (3) combined drop and flap, (4) rotary, (5) roller blind, (6) focal plane, (7) moving blade central, (8) iris. They can be applied in different positions: (a) in front of the lens; (b) between the lens and the front of the plate; (c) in front of the sensitive plate. They all, however, come under two main classes: Laterals, including those in which the exposure commences and ends at the circumference of the lens aperture; and the slit, in which the exposure begins and ends at the circumference of the aperture. Some of them are "lateral" in their single form and "central" when double. The form and position of the effective aperture of a shutter, relatively to the lens and plate, have a strong bearing on the character of the image. The effective aperture for a photographic plate or film is the image of the lens, placed in the plane of the plate, and the effective light passing through the lens, and its even distribution over the plate. This is especially the case during the incomplete phases of opening and closing the aperture. It seems to be agreed that the best position for lens shutters of the lateral type is behind the objective, and for those of the central type, between the component lenses. In this latter position the whole of the plate is illuminated during the full period of exposure, with a gradually increasing or decreasing light over it. In the former position the illumination gradually falls off until the shutter is closed. The most effective shutter is one in which the first and third phases of exposure are made at a maximum, and the second phases are the shortest compared with the second phase of full opening.

With the focal plane shutters, however, different portions of the plate are exposed in succession, the lens working at its full aperture and being closed towards the end of the exposure. To secure successful results in using instantaneous shutters, the operator should make himself acquainted with the working of his shutter and its efficiency in various circumstances of exposure with different lenses, plates and developers; he should also ascertain the actual value of the various exposures marked on the indicator, and,
PHOTOGRAPHY

What is more important, how far they can be depended on for regularity. There are many simple ways in which the actual time of exposure from opening to closing can be ascertained sufficiently closely for practical purposes. They depend upon the measurement of the trace left on a sensitive plate by the passage of a brightly illuminated object revolving at a known speed or falling vertically through a known distance, when photographed with different speeds of the shutter against a dark background. These, and the more elaborate methods for obtaining more accurate determinations of the shutter-exposure periods and of the corresponding effective exposure—i.e., showing the actual effect of the shutter through its different phases from opening to closing—have been described by Sir William Abney in the work already mentioned. Lond. inst. Phot. moderne et Ph. instantanée. An apparatus for testing shutters at the National Physical Laboratory was described by J. de Graaf Hunter in the Optician, 1896.

2. Drop Shutters. The simple flap shutter, consisting of a hinged flap opening upwards in front of the lens, though favours in early days for landscape work, and still useful for intermittent exposures as a stoppage against cloud effects or increasing foreground exposures, have been almost superseded by quicker and more compact forms. They are used with single and double flaps for portrait and studio work, for which purpose they are made to act noiselessly and not attract the attention of the sitters. Guerry's (figs. 59 and 60) is a good example of the type. W. Watson's "Silent"

3. Combined Drop and Flap Shutters. In early dry-plate days several forms of this kind of shutter were brought out, under the names of Phoenix, Phantom, &c., but are now little used. In these shutters, in addition to the drop slide, there was also a lifting flap, which on release opened from below, and, having fully uncovered the aperture, released the drop slide, which fell and closed the shutter. They were useful and effective in the smaller sizes, but heavy and cumbersome in the larger. Speed could only be estimated very roughly by the use of inio-rubber bands for tugging.

4. Rotary Shutters. These are of the lateral type, and consist of a circular metal disk revolving on an axis eccentric to the axis of the lens, and furnished with a radial sector-shaped opening, which passes laterally in front of the lens aperture. The shutter, as the spring is released (fig. 61). They are used in various patterns in cheap hand cameras, usually in front of the objective, though they may be placed behind it or between the component lenses. So long as the opening is at least equal to the size of the lens aperture, the illumination is sufficiently even, but the openings are usually elongated so as to give a longer period of full exposure. Working by a spring they are more portable and convenient than drop shutters. Beck's "Cleverex" between-lens shutter (1906) is of this type, the disk being revolved in a spring and the variation of exposure obtained by altering the size of the opening passing over the lens aperture, and not the tension of the spring. It is speeded for exposures of 1/50 sec. &c., and "bulb" and "time." It is fairly accurate and consistent in action, but loses efficiency at the highest speeds by the diminution of the opening.

5. Roller-Blind Shutters. For general use the well-known roller-blind shutter is the most simple, and is made by Thornton-Pickard and others, is undoubtedly one of the most popular and efficient. It possesses most of the qualities laid down as essential to a good shutter, gives good illumination, appears to be fairly regular in its action for time or instantaneous exposures. It consists of a light mahogany or aluminium box, arranged so that it can be fitted in front of or behind the objective. It is made in different sizes, and each size can be adjusted to smaller objects (fig. 62). It is also made with a disappearing cord, and in an improved pattern, the "Royal," all the fittings are inside the box. By pulling the cord an opaque black curtain with an elongated rectangular aperture is unrolled from the lower roller to the upper one, and held by a coiled spring on the lower roller (fig. 63). Pressure on a pneumatic release opens the shutter, and another pressure closes it. In arrangement is now made by which time exposures of 1/1, 1/2, 1/3, 1/4, 1/5, 1/6, 1/8, 1/9, 1/10, 1/15, 1/30, 1/60, 1/120 seconds can be given automatically, the pressure of the bulb opening the shutter, and closeness of itself at the expiration of the exposure required. The theory of shutters of this type has been very fully discussed by Coventry (op. cit. p. 50), who shows that for any given tension of the spring the actual exposure decreases as the size of the lens aperture diminishes, while the effective exposure remains constant for all apertures. This is due to the arrangement of the lateral shutter. He also shows that with plates of very different rapidities, though the exposure may be the same, the actual exposure effective is less with the rapid plate and a small stop than with the slow plate and a large stop. Consequently, the movement of the object would be proportionately less on the rapid plate than on the slow one. Also that for any given lens the smaller the shutter the more rapid the exposure can be made, though with the same lens a larger shutter is capable of giving a perfect exposure but lees rapid exposure. It is better, therefore, for moderate exposures, to have a larger shutter than the size of the lens requires. Sir William Abney had given diagrams of the action of a shutter of this kind in his book referred to; they show clearly that the centre of the plate gets more exposure than the margins; but practically this is not very noticeable, and the action is very regular.

6. Foil Plane Shutters. These are also roller-blind shutters with mechanism similar to the foregoing, but arranged so that the slit in the curtain may move rapidly close in front of the sensitive plate, exposing different portions of it in turn, the intensity of the exposure being regulated by the width of the slit, whether adjustable or not, and the rapidity with which it is moved by the unwinding of a spring. The advantages of these shutters are now being fully appreciated. The principal being that they are quite independent of the lens, so that one shutter will serve for different lenses, and a single variable slit may be used at its full intensity, without the loss of efficiency inherent in the ordinary forms of lens-shutters. They thus add effectively, if not actually, to the speed of a slow lens, or if a lens be stopped down there is less loss of efficiency, with a gain in increased depth and definition. They are particularly well adapted for the very short exposures required in photographing near and quickly moving objects, racing ships, &c., a simple roller and other hand cameras are fitted with them. They are constructed in different forms, either for short exposures with high speeds alone, or for short and prolonged exposures; with a single slit of fixed or variable width moved at regulated speeds, or with a series of slits or openings varying in width, their speeds being adjusted by the
tensions of the springs. Thus the new Goerz-Anschütz shutter has ten apertures, providing for thirty different speeds or exposures, ranging from 1/8 to 150s of a second, besides autolb exposures from 1/30 to 1 second and the exposures (fig. 64). Most of these shutters are now provided with a self-capping device for protecting the sensitive plate during the setting of the shutter. As the slit moves progressively over the plate, it is not as narrow or moving too slowly, it may cause distortion of the images of quickly-moving objects, especially if near the slit, but with due care in regulating the width of the slit and the duration of exposure this is practically not often perceptible, especially if the slit is arranged to move in the same direction as the object. The theory of these shutters is discussed by Coventry (op. cit. p. 60), more fully by Fabre (T. E. P. Suppl. C. p. 128), and their practical use in Focal Plane Photography ("Photo-Minature Series," No. 77, 1893).

7. Moving Blade Central Shutters.—These shutters, in which two thin metal or plate plates or opaque curtains with round or rectangular apertures, or in other cases two curved blades, pass very quickly over each other in opposite directions, are largely used in many patterns fitted between the lenses of a combination or attached to them in front or behind. Formed of two single lateral shutters opening and closing in the centre of the lens aperture, they become central, the exposure taking place during the short period in which the openings are passing each other or the curved blades opening out and closing again. To obtain the greatest efficiency the site of the openings should correspond with the full aperture of the lens. If each plate moves as fast as a drop shutter the combination gives double the speed, corresponding to half the exposure. The sensitive plate will be most evenly and strongly illuminated when the leaves of the shutters move in a plane close to and near the diaphragm, as in Bausch and Lomb's "Unicum" and other similar between-lens shutters, in general use (fig. 65). This necessitates the fitting of the lens to the shutter, but with adaptors

8. Iris Shutters.—These are a further development of the double central shutters and are constructed on the principle of the "Iris" diaphragm, with several leaves opening out from the centre of the lens and closing again. They are usually fitted between the lenses of double objectives, and can be made very lightweight and compactly. The fastest and the most desirable iris is the best, and the "Iris" is the best form for ensuring the most equal distribution of light over the plate, provided, as before, that the opening is equal to the full aperture of the lens. They are made so that the modes of opening and closing may be as short as possible compared with that of full opening. They require great care in selecting the correct ratio to the lens, and so are expensive. They can, however, be used with interchangeable sets of lens caps of different foci fitting the same mount. Several forms are made by British and foreign makers, with three, four, five, or six leaves. Goerz-Anschütz's shutter (fig. 67) may be taken as a type. Georgan's "Central" shutter is very light and smooth in working, the principles on which these are best for telephoto work. Further details regarding the different forms of shutters, theoretical and practical, are found in Abney's, "Photographic Snapshots," and by Abney, Coventry, Edyr, Fabre and Londe.

Exposure Meters.

When gelatin dry plates came into general use, and were made of many different degrees of sensitiveness, the want of a guide to the proper exposure for the various makes of plates under different conditions of lighting began to be felt, and several methods were devised for meeting it. Some of them depend solely upon data derived from observations of the action of the principal factors affecting the result, namely: (1) the speed of the plate; (2) the action of the sun's light for the time of year in the latitude and its position at the particular time of day; (3) the effective aperture of the lens; (4) the nature of the subject and its illumination as affected by local and atmospheric conditions. With the great increase in the amount of work and the number of different plates, it was practically based upon, actinometric observations of the action of the light upon sensitive paper exposed near the camera or the subject at the time. Both methods are in many cases of undoubted use, but the information given by instruments of this kind can only be considered as approximate, and much is left to the judgment of the operator, whose surest guide must be an intelligent study of the principles on which these lenses are based, together with carefully-recorded observations of the characteristic phenomena of the lenses, shutters, plates and methods of development of the varying conditions of practical work. Before using any of these instruments it is necessary to know approximately the relative sensitiveness or "speed" of the plate in use. In the early days of gelatin dry plates their rapidities were stated as so many times those of wet plates, or (as they are still) "ordinary," "instantaneous," "extra-rapid," or "platino," or the number of plates required to produce a certain exposure, but none of these measures will be satisfactory. To overcome this difficulty, in 1890 F. Hurter and V. C. Driffield introduced an entirely new system of calculating the sensitiveness of plates of different rapidities. They make a series of exposures in seconds on different plates in good position over a point of light at one metre distance. After development for a certain fixed period with a standard developer, fixing, washing and drying, the "durations" or logarithms of the opacities of the different parts are obtained by the spectrophotograph method, the results being plotted on a graph paper, producing a curve, one portion of which will practically be a straight line. The position of this line with reference to a scale of exposures given on the graph indicates the rapidity of the plate, while its slope indicates the velocity of the plate for the truthful rendering of tone. The elaborate investigations by which these results were obtained are of great interest, and were published in the "Journal of the Society for Chemical Industry" (1899, 1891), and in the "Photographic News" (1890). The "Photo Miniature Series" of the System of the system by V. C. Driffield was published in 1903, as No. 56 of the "Photo Miniature Series." The sensitiveness shown on the H. & D. scale is directly proportional to the speed number given. The method has been adopted by several dry-plate makers in
denoting the sensitiveness of their different brands, and is more or less the basis on which the plate-speeds for the modern English dry plates and exposure meters are calculated. Several systems of photometry and measurement of the speed of the dry plates have been discussed at the meetings of the Congrès International de Photographie, in 1889, 1891, 1900 and 1905, but no definite standard has been finally adopted. In Corfu, the use of J. Scheiner's sensitometer has been adopted, and appears to be extending. It is based on a system of photographing the graduated tints given by rotating sectors. A full account of the instrument, and an account of a system of sensitometry based on its use, is given by the addition of a sensitometer which is useful for the comparison of orthochromatic dry plates, color screens, light filters, &c. It consists of a screen plate, 43 x 34 in., containing a series of twenty-five tints graduated in density; a series of colored squares, blue, green, yellow and red, and a strip of neutral gray, all being of approximately equal luminosity; a series of four squares of special pure colours, each representing a portion of the spectrum; also a scale of time design, over which is superposed a half-tone strip. To use the instrument, a quarter-plate of the brand to be tested is exposed behind the screen for a few seconds to the light of a standard candle placed 10 ft. off, and fixed at a distance of 6 in. An examination of the plate will show the sensitiveness, range of gradation, possible range of exposure, sensitiveness to color, size of grain, amount of halation, and the most suitable light for development of the plate can be found, from the test. It is certain for any brand of plates to be readily tested by the user and compared with any standard he may find convenient. In making these and subsequent tests, the user should be allowed to act for a fixed period and at a uniform temperature (Ph. Journ. 1901, 25 p. 240).

The next important factor is the actinic power of the light. It depends not only on the height of the sun for the latitude of the place, but also on the time of the year. When the photograph is taken, and exposures in bright sunlight are found to vary approximately as the cosecant of the sun's altitude above the horizon. The light of the sun itself is an actinometer (1901), p. 275, the sun's rays, and, with a photographic plate of average sensitiveness, is shown (ep. cit. p. 75) how the "light coefficient," for full sunlight, can be found, and has given a table of values of L for the latitude of London, in which - L is the inverse of the cosine of the altitude of the sun at the given time. Throughout the year, also the relative coefficients for "diffused light," "cloudy," "dull" and "very dull." Tables of exposures for different subjects under varying conditions of light have been published by W. K. Barton, A. S. Patl, W. W. Mills, Sir D. Salter, and others, and in preparing these Dr J. A. Scott's tables, showing monthly and daily variations of light for countries about lat. 53°, are generally used. The more modern tables, such as are published for the different exposure notebooks, also take into account the plate speeds, but unfortunately there is no uniform standard of plate speeds, owing to the difficulty of fixing a definite standard of light. The subject is fully treated in the British Journal, 1893, p. 575, by Professor Meunier, H. Boursault's Calcul du temps de pose en photographie, and similar works by A. de la Baume Pluvinal, G. de C. Espinassoux, and others.

Based on the same principle as these exposure tables, various portable exposure meters and exposure machines have been brought on the market, in which the actinic power representing the coefficients for plate-speed, light and exposure are arranged as in a slide rule, so that, when properly set, the normal exposure required can be found by inspection, and increased at diminished. A few, the circlip plates and the Driffield's "Actinograph" the light coefficient is given by a printed card showing the curves for every day in the year and for every hour of the day. The unit being the 18th part of a square inch of daylight, when the sun is 90°. It is based on the "days of the sun" and the sun's altitude. The "days of the sun" scale shows the ratios of aperture to focal length in general use, and is calculated for single, double and triple systems of lenses. The "light" scale is based on the equinoxes of March and September. One actinograph degree of light will produce a perfect negative of an ordinary landscape. An additional scale is given for five different degrees of illumination—very bright, bright, mean, dull, very dull. A table of factors for "view," "portraiture," "interiors," "copying," is also given, and these regulate the figure to be taken for the exposure. The scales are engraved on boxwood, and there are two sliding pieces (fig. 68).

It is specially adapted for use with plates of speed numbers agreeing with the H. & D. scale, but can be used with any plate of which the relative speed number is known. Convenient exposure meters have been made since 1890 by A. Watkins, of Hereford, in different forms based upon an actinometrical test of the light at the time of exposure. In the complete "Standard Meter" (1890) scales corresponding to "speed of plate," "diaphragm f numbers," "light," "subject" and "enlarging," marked P. D. A. S. and E., are arranged in rings adjusted round a cylinder. The speed-takes are made from a table and the "light coefficient," or "actinometer number," is ascertained at the time by exposing a piece of sensitive paper in the actinometer at the end of the instrument for the number of seconds required to match a fixed tint as shown by an attached pendulum. Many improvements have been made in it and the latest version (1908) is made in the form of a "Dial meter" (1901) is a simpler form in a circular metal case with four apertures: marked "plate," "stop," "ace," and "exp," and with the corresponding scales and an actinometer for testing the light. The numbers showing the speed of the plate in use, the f value of the diaphragm, and the actinometer exposure in seconds are brought into the respective apertures and the exposure required is read off in the "exposure" aperture. An "indoor meter," is also made, and a "hand camera calculator" for use with the strips. The "Queens Bee" and "Bee" meters (1903) are smaller and more portable instruments, which have superseded the "Dial" meter and have the plate numbers and exposures marked round the case, and the scales of "f numbers" and "second." This is a revolution till the f number on the right is opposite the speed number of the plate; opposite the "actinometer number" on the left, found as above, will be found the exposure in seconds (fig. 70). The "Queen Bee" meter is similar to the "Bee" meter, but of better construction and fitted with a pendulum.

G. F. Wynne's "Infallible" exposure meter (1893) is also in dial form, but the sensitive paper is exposed directly, no pendulum is used, and the scales are open on the dial. In use, the glass carrying the movable scale is turned until the actinometer time in seconds upon the exposure scale is opposite the dia logarithm of the number of the plate, as given in the list of plate speeds; the correct exposure will then be found against the plate number on the scale. There are practically only two scales; the scale of diaphragms representing the dia logarithm of the number of the speed of plate and the variation of exposure due to subject; and the time scale, representing the actinometer time and the exposure (fig. 71). The actinometer is protected by a yellow glass screen when not in use. In a smaller form the scales are on the
circumference of a locket, and the actinometer at the back. An "Infallible" Printmeter is also made for showing exposures in contact printing on sensitive papers, but can also be used to measure the"Actinic" and "Zambivite" Exposure Meter gives the exposure to stop, used also the depth of focus to be obtained with different diaphragm apertures. The required distance to the meter is a number of times the scale of meter. The third scale corresponds to the times of darkening the sensitive paper in the actinometer attached to the meter, and shows the diaphragm aperture suitable for the given size. The scales are given for three different sensitivities, in focus with the different stops used, arranged so that the focal depth of four different lenses can be found. Several other exposure meters are made on the principle of the slide rule, with scale corresponding to the "diaphragm", "light", "subject", "exposure", and the exposure is found by simple inspection without an actinometer. They are designed for use with particular brands of plates, but can be used for others, with slight variations.

Another class of exposure meters comprises those in which the intensity of the light is estimated visually by extinction in a specially-constructed chamber. Dr. J. Découd's (1888), in which the exposure is judged by the disappearance of a series of small clear openings on a graduated scale of densities when laid on the most important part of the image as a measure of densest plate. Its readings are not very accurate and the paper scale changes in density after a time. Another form is "E. Degen's Normal Photometer" (1903), consisting of two sliding violet glass prisms, one adjusted for the diaphragm aperture, and the other for the object, to be used in the object to be exposed directly through openings at one end of the instrument, and the lower slide is drawn out and pushed back slowly till the object viewed is almost obscured. The attached pointer will then indicate the exposure required, or, reversing the order, the diaphragm aperture for a given exposure can be found. Auxiliary scales are attached for very short or very long exposures. The principle of construction is that the logarithms of the areas of the indicated transparent regions are proportional to the sensitiveness of the plate, and are used for determining the exposure in the form of a scale of graduated optical gelatines, etc., or of a photographed scale graduated by increasing exposures. The "Burton actinometer," for pigment printing, made on this principle, contains several small negatives of different densities in a series of transparent plates, is selected within the range of the exposures, and printed, and the progress of the printing is estimated by exposing a piece of sensitive paper under it and examining it from time to time.

Sensitive Plates, Films and Papers

Sensitive Dry Plates.—A special feature of modern photography is the use of trustworthy ready-prepared sensitive dry plates and films in different grades of sensitiveness, so that there is, necessity for the photographer to prepare his own plates, nor, indeed, could he do so with any advantage. The practice of outdoor and studio photography has thus been greatly simplified, and although with wet collodion there was the advantage of seeing the results at once and retaking a picture if necessary, the uncertainties connected with the use of the silver bath and collodion, and the amount of cumbersome apparatus necessary for preparing and developing the plates at the time, have now been obviated, and photography has become a much simpler and less time-consuming art, in using dry plates as compared with wet, by deferring development. In tropical climates, also, dry plates can be used when work with wet plates would be impossible. On the other hand, dry plates are more expensive than wet plates, and prepared plates must not be overlooked. Besides their use in taking negatives, gelatin dry plates are also largely used for printing transparencies, lantern slides, enlargements, &c. For negative work, they are worked up with an action of sensitizing alone or with the addition of silver iodide or chloride, and are to be obtained in five or six degrees of rapidity: "slow," for photography work; "ordinary," for general purposes; and "extra rapid," for instantaneous exposures; and "double extra rapid," for very quick snapshot work in dull weather or under artificial light. These plates require careful development and require great care in use to avoid fog. In order to prevent halation, or irregular action by reflection from the back surface of the glass, dry plates are coated with a non-actinic "backing," which can easily be removed before development.

Self-developing dry plates were introduced in 1906, in which the developing agent is mixed in the film itself, as in the Ilford "Type A" plates, which are manufactured by washing soda for development, or, as in the Wellington "Watala" plates, applied on the back of the plate, plain water only being required for development, this application also preventing halation. A special application of this is the "stock print" and "contact print" method, the latter is used for reproducing a black-and-white image with an emulsion of silver chloride with or without free silver nitrate and other halides.

The rendering of photographic plates isochromatic or sensitive to the different colours of the spectrum is of great interest to applicants, of course, its history is an interesting one, for various grades of sensitivity for various purposes exist, and it has been greatly improved by the use of new dyes, especially those of the isocyanin group, prepared by Dr. E. König of the Hoechst Factory, and by Dr. Jena and "pinachrom." "Isocyanin," "isouberdol," "pinachrom" and "pinachrom," the latter is a substance to confer on a silver bromide plate as high a degree of sensitivity for red as erythrosin does for yellow; also F. Bayer's "sensitive plates." Dr. A. Jena specially prepared plates (see E. Jb., 1905, pp. 138, 334). Panchromatic plates are now largely manufactured and used for all photographic work in which a true rendering of the relative colour luminosities is essential, and more particularly for portraits, landscapes, etc., colored plates in which plates are required to be sensitive to red, green and blue-violet. They are made in different degrees of general and colour sensitiveness, according to the purpose for which they are required, and are denoted by the word "panchromatic" being written thus: "z. i. panchromatic" for red; "z. g. panchromatic" for green, and the "panchromatic" for red, orange and yellow, as well as for green, blue and violet. To obtain the best results from all these plates, it is necessary to screen off the blue and violet rays, or, with yellow or orange transparent plates, to use emulsion made of coloured glass, or glass coated with coloured gelatin, celluloid, &c., or with glass cells containing solutions of suitable dyes and tints. Other methods of reproducing panchromatic plates and special red, green and blue-violet filters have to be used for taking the three negatives, their intensities and absorptions being carefully adjusted to the particular plates in use; the same applies, but less strictly, to the yellow screens used with ordinary isochromatic plates. Dyes specially suitable for these colour-filters have been prepared by Dr. E. König. Various kinds of colour screens for ordinary, microscopic and trichromatic photography have been made by Messrs. Jena. A series of which is coated with a special yellow glass in three tints for the purpose.

Plates for Colour Photography.—In 1868 Louis Ducos du Hauron, among various trichromatic methods patented for photographically reproducing coloured objects in the colours of nature, described a method in which the trichromatic principle, instead of being carried out on three separate plates, was to be combined in one plate by means of a transparent medium passed through a trichromatic screen divided into narrow juxtaposed lines or minute spaces, corresponding to the three primary colours, red, green and blue-violet, the transparent colour of each of these lines or spaces acting as a colour filter for the plate, and the light passing through the lines to contact with this screen to produce a negative with lines or spots corresponding to the relative strength of the three coloured lights passing through it, so that a diapositive print on glass properly exposed produced the true colour. The method has thus attained to the stage of producing proper colours. This method could not be carried out successfully for want of efficient panchromatic plates and other difficulties.

Between 1892 and 1898 several patents were taken out by J. W. M. Warner and J. Jena, and the "Jena Tricolour" or "Jena Mark" was introduced, which, it was claimed, was a real trichromatic method. The Joly method was fairly successful in action, but had several disadvantages owing to the coarseness of the lines, the necessity for having two screens, one for taly and another for views, the cost of making them (B. J. A., 1899, p. 671). The "Florence" chromatic plate (1905), worked out in America by J. H. Powrie and Florence M. Warner, was an improvement on the Joly method, the colour screen being photographically printed on a glass plate, coated with panchromatic emulsion and exposed to the coloured object through the screen (Penrose Pictorial Annual, 1905-1906, p. 111). Some good results have been obtained by an improved form of this method.

After several years of laborious research, Messrs Lumière, of Lyons, adopting Ducos du Hauron's coloured grain method, succeeded where he had failed, and in 1907 brought out their "Autochromes," in a very compact form, it being possible to photograph objects in the colour of natural objects by one exposure instead of three, as in the ordinary three-colour processes. Glass plates are coated with an adhesive medium over which are spread thin layers of a special photographic emulsion, containing, besides the grains of silver, some substance which gives the grains a special colour. The plates are exposed in the camera from the back, through the tricolour films, using also a special plate which is sensitive to red rays, and behind the lens, then developed as usual, producing a negative colored image in the complementary colours, which is then treated and reversed so as to produce a positive coloured image by transmission, showing the picture in its proper colours. The results thus obtained
are remarkably good and practically solve the problem of direct colour photography in a simple and fairly inexpensive manner (see Agenda Luminis, 1907, p. 515). In C. F. Jenkins’ “Thames” colour plate (1908) the tricolour screen is formed by rows of circular dots coloured alternately orange-red and green and the intermediate spaces blue. It is used as a photographic filter, placed in contact with a panchromatic plate, the uncoated side towards the light. It carries water marks for adjusting to it the finished picture after development and reversal of the image. These screens, being more transparent than the “Halochalet” screen, require a longer band of elements for the rendering not to be so perfect. In the Jougl’s “Omnicolore” plate (1909) the tricolour screen and sensitive surface are combined on one plate as in the “Autochrome,” but the screen is made up of a series of squares, each square having its own set of parallel broken lines of orange-red and yellow-green at right angles to them, the red narrower than the green. The relative sizes of the coloured dots in the three plates are approximately:

E. Fenske’s “Aurora” plate (1909) is a tricolour screen formed by coating a glass plate with a mixture of finely divided particles of gelatin, used in orange-red, green and blue, which can be coated with great saving of bulk, weight and no loss of efficiency, though such films are sometimes liable to deterioration by long keeping before or after exposure. They are made in two thicknesses, stiff or flexible, the stiff film being used as a plate, but held in a frame by glass, while the flexible film can be used without an intervening space. The grain generally is coarser and more irregular than in the “Autochrome” plates, but optically corresponds to the plate “Halochalet” or “Omnicolore” screens do. These plates are issued uncoated for use with any suitable panchromatic plate. A later process is due to Dufay. With the exception of the “Autochrome,” these processes are still more economical than the others. They have been widely adopted by the printing industry for reproduction purposes, large prints being made by an automatic or semi-automatic process, or by photographic transfer printing on paper or textiles.

**APPARATUS**

**PHOTOGRAPHY**

**Celluloid Films.**—In order to avoid the weight of glass plates, which may become burdensome on a tour, and also the risk of breakage of valuable records, thin films or sheets of celluloid coated with sensitized emulsions can be used. The emulsions can be made or bought with great saving of bulk and weight and no loss of efficiency, though such films are sometimes liable to deterioration by long keeping before or after exposure. They are made in two thicknesses, stiff or flexible, the stiff film being used as a plate, but held in a frame by glass, while the flexible film can be used without an intervening space. The grain generally is coarser and more irregular than in the “Autochrome” plates, but optically corresponds to the plate “Halochalet” or “Omnicolore” screens do. These plates are issued uncoated for use with any suitable panchromatic plate. A later process is due to Dufay. With the exception of the “Autochrome,” these processes are still more economical than the others. They have been widely adopted by the printing industry for reproduction purposes, large prints being made by an automatic or semi-automatic process, or by photographic transfer printing on paper or textiles.

**Photographic Printing Papers.**—For a long time the supply of ready-prepared papers, all kinds of photographic printing papers can now be obtained ready for use, so that the photographer has not to buy emulsions and mix them up himself. The old albuminized papers have been generally superseded by ready-prepared sensitive papers coated by machinery with emulsions of silver haloids in gelatin, with or without citrate or other organic salts, the chloride being used for most of the “P.O.P.” or “printing out papers,” which contain more or less free silver nitrate, and in the “self-toning” papers some salt of gold. Some of these printing out papers are also made with emulsions of silver chloride in collodion, and known as “C.C.” or “collodiochloride.” The basis of most of the developable bromide papers used for enlargements and direct copying, containing no free silver nitrate, with which an emulsion is brought out by chemical means, much in the same way as with dry plates, is silver bromide. These papers are made in great variety of tints and surfaces, “smooth” and “rough,” “glossy” and “mat,” for producing different effects. They are largely used for direct printing by artificial light or daylight, for enlargements, and for printing photographic post-cards, &c., in large numbers by machinery, the prints being made on a long band within almost instantaneous exposure, and developed and fixed by being passed through the proper solutions on large rollers or otherwise. Papers for the platinotype processes, sensitized with salts of platinum and iron, are also manufactured for printing in their developed state. Prints on these papers have the advantage of being permanent.

Messrs York Schwartz and J. Mallabar’s process of developing and toning prints made on a special sensitive paper prepared with an addition of silver phospate was introduced by Messrs Houghton in 1907 under the name of “Ensyna.” Very short exposure to day or artificial light is required, and with a special developer paper is developed in about four minutes after exposure, and then washed in water, and the colour of the printing is determined by the exposure, short exposures giving a shorter exposure giving a brownish-dark brown and reddish-brown tinge. The process is rapid and is used in a long band within almost instantaneous exposure, and in trichromatic printing on paper by the Sanger-Shepherd method and Dr Koenig’s “Pinotype.” For Manly’s “Ozotype” and “Osobrome” processes special gelatinized and pigmented papers are made. The films used for making the prints are prepared for the use of architects, engineers, &c., in rolls of considerable width, for the direct reproduction of tracings and drawings as blue or black prints by these and similar methods.

**Heliotype for Development.**—The fact that the two principal factors in the development of modern photographic dry plates with a suitable developer are time and temperature, and also that a prolonged immersion in dilute solutions is in many cases a more convenient and equally efficient method of development, has led to the construction of apparatus for enabling the operation to be carried out almost automatically and for timing its duration.

In 1894 A. Watkins brought out his factorial system of development based on the principle “that with a correct exposure on a given plate with a given developing agent, the time of development can be expressed in terms of the ratio of the time of appearance of the high lights of the image, provided the developing power of the solution remains constant during development, and this rule holds good for all variations of pH and amount of the developing agent within those limits which have been found most suitable” (Photo. News, 1894, 38, pp. 115, 729; and further, Ph. Journ., 1900, 24, p. 221). By a series of observations he ascertained the multiplying factors of new developers in ordinary use, and in 1895 he patented his “factorial calculator” and a “dark-room clock” for facilitating the working of the method. The former is made of aluminium, and consists of two circular disks, the upper smaller one carrying a pointer, and the outer disk is marked with a scale of Watkins’ factors for the different developers, as given in the instructions accompanying the instrument, and is used to denote the time of development “minutes. The scale on the inner

PHOTOGRAPHY

The "calculator" can be used with any ordinary clock or watch, but the "dark-room clock" (fig. 73) has been specially constructed for the "kitchen" for an "exposure" stopwatch of Watkins' "Ekrometer," and has a 4 in. dial with 10 and 100 second divisions, very plain for dark rooms, centre seconds hand, stop action and outside indicator to mark the time which is completed in 10 seconds when the minute hand does so in 10 minutes, or sufficient for the longest ordinary development, though it runs on, if necessary, very much longer, both hands starting together at 0.

In 1908 Watkins brought out another system of "thermo-development" by time dependent on the use of a standard "time developer," the duration of which is modified according to the make and speed of the particular plate in use. The temperature variations are indicated by a movable scale, or "thermo-calculator," on the bottle of developer, the cycle of development being given approximately on the "Waterkite Plate Speed List," which thus shows the "speed of plate" and "speed of development" with the standard developer at 60°. This method is well adapted for plates and films and stand development in tanks or machines, no observation of the plate being required, and the times are most conveniently observed with the "dark-room clock.

Full details of these two distinct methods of development will be found in the 4th edition of the Watkins Manual of Exposure and Development.

C. W. Piper's "photographer's stop clock" (1906) is a more elaborate clock, if for the "time exposure" development of all photographic operations in which accurate control in regard to time is of importance. It is fitted with a gong and arranged to work by "time" or "bulb." Once started, by pressure on a lever or "bulb," it will continue to ring until stopped, striking the gong at the completion of every minute, when the seconds hand reaches the zero point. A second pressure on the bulb stops the clock, so long as the pressure is continued. When pressure on a lever stops it permanently. It is thus useful for timing any intermittent operations, whilst the clock adds up the separate times and prevents the occurrence of errors difficult to avoid when timing with an ordinary watch. By an additional attachment a prolonged time exposure with the camera may be terminated, or an "instantaneous" or short "time" exposure given at any prearranged time. Messrs Houghton's "Ensign" clock for time development has a dial with 60 divisions, a single hand, and is fitted with a gong. It can be set to ring an alarm bell at the expiration of any period from one minute to one hour, can be started or stopped immediately and is easily read in the dark-room. It requires no winding up, the action of setting providing the tension for the recording movements. It can be stopped and started at will and the bell arranged to give a short or prolonged ring. S. Stanely's is another convenient form, with a 4½ in. dial, divided into 60 seconds and 60 minutes, the thick hand recording the seconds and the thin hand the minutes.

Several forms of developing tanks and machines have been constructed for developing a number of prints or plates at once, and there are many different forms of the factorial system or independently of it. The Kodak "Automatic Developing Tank" (1905) is a useful arrangement by which hands of exposed film can be immersed in the developer, and have developed in a dark-room (fig. 74). The exposed film is wound from the spool into a flat celluloid apron contained in a box A, then placed in the tank B, where it is left in a dilute developer for about twenty minutes, and requires no attention. It gives very good results. For the "Brownie" films a special daylight developing box is made. The ordinary stop clock is fitted with a stopper which holds the exposed plates in the dark-room, from the plate holders and placed in, pairs back to back, in a special framework holding six pairs, which is lowered into a metal tank containing the developing solution, and is brought into contact with the developer lid so that it can be inverted during development. A clock face, with pointer, by which the period of development may be noted is fitted outside the tank. Another apparatus of the kind is made for developing celluloid films exposed in the "Premo Film Packs" (fig. 75).

FIG. 75.—Premo Film Pack Tank (1908).

Photographic Printing Apparatus

For ordinary printing purposes pressure frames, with or without glass fronts, are used for holding the negative and sensitive paper in close contact during exposure to light. They are fitted with hinged backs enabling the progress of the printing to be seen. The pressure is given by means of springs or with screws or wedges acting on the back. They are made in different kinds shown in the dealers' catalogues. For copying large tracings and engineers' drawings by the cyanotype and similar processes large glazed frames are used, mounted on a stand with arms, so that they may be easily turned over for retiling or fixed at a suitable angle to the light. The pressure is given by an elastic cushion or vacuum arrangement, by which the negative or positive is pressed to a rubber sheet covering the back of the frame, thus securing a perfectly uniform pressure of about 14 lb to the square inch without strain on the front glass. Such frames are also useful for various other mechanical printing processes with large negatives or metal plates.

For rapid printing of post-card and other negatives up to 8½ x 6 in. a handy and simple apparatus has been made which has been found for light and gas and electric light, with a sloping front, in which a special printing frame is fixed and arranged so that the prints can be rapidly exposed one after another (B. J. A. 1909), p. 691. In another form arrangements are made for exposing a large number of printing frames on a suitable stand, in one or two tiers round a central arc lamp, which may be provided, as in the "Westminster" revolving printing frame, with a shade to protect the eyes of the operator when exposed to the print making light directly.

Pictorial Photography

Pictorial photography differs from other branches of photographic practice in the motive by which it is prompted. Employing the same methods and tools, it seeks to use photographic processes as a means of personal artistic expression. Thus in the early days of Fox Talbot's calotype, about 1846, Dr. James Milner, a successful Scottish painter, took up this method of portraiture, and, guided by an artist's knowledge of subject and taste, and unfettered by photographic convention, which indeed had then not even reached the stage of a dry process by which genuine pictorial quality has perhaps never been surpassed, especially if some allowance be made for the necessary imperfections of the "Talbotype" (see plate). Whether they were in their day typical examples of Talbotype with all the latest improvements, Hill probably never cared. When, again, a few years later, Sir William J. Newton, the eminent miniature painter, read a paper before the newly formed Photographic Society of Great Britain (now the Royal Photographic Society), his recommendation to depart from the custom of defining everything with excessive sharpness caused his address to be almost epoch-making. He said: "I do not conceive it to be necessary or desirable;" he said: "It cannot be safely, or even be a safe attempt, of every minute detail, but to ensure at producing a broad and general effect. . . . I do not consider that the whole of the subject should be what is called 'in focus'; on the contrary, I have found in many instances that the object is better obtained by the whole subject being a little out of focus." The doctrine has been persistently repeated ever since, but only within the last decade of the 19th century was the suppression of focus received by photographers generally with anything better than ridicule or contempt, because it was unorthodox. O. G. Rejlander, Mrs Julia Margaret Cameron, H. P. Robinson, and others, by precept or practice, strove against such photographic conventions as had arisen out of those technical exigencies to which pictorial qualities were so often sacrificed. As late as 1868, in the *Manual of Photographic Manipulation*, by Lake Price, the old advice to arrange a group of persons in crescent form, so as to adapt the subject to the curve of the field of the lens, was repeated with the additional recommendation of plotting out on the ground beforehand the "curve of the focus" as a guide. As a defiance of this dictum, Rejlander, in 1869, produced a group of the members of the Solar Club in which some of the chief figures were set widely out of the "curve of the focus." The mere technical difficulties of this performance with wet collodion plates, and in an ordinary upper room, need not be touched upon here, but it is to be noted as one of those triumphant departures from convention which have marked the progressive stages of pictorial photography. At about the same period, Mrs Cameron, carrying the recommendation of "a little out of focus" rather further, regardless of how her lens was intended to be used by its maker, secured the rendering dictated by her own taste and judgment, with the result that many of her portraits, such as those of Tennison, Carlyle, &c., are still in their way unsurpassed. Contemporaneously, Adam Salomon, a talented sculptor, "sunned" down the too garish lights of his photographic prints, and strengthened the high lights by working on the back of the negative.

During the concluding quarter of the 19th century, probably the most powerful influence in pictorial photography was that of H. P. Robinson, who died in February 1903, and, but for a brief period about the year 1875, was one of the most prolific "picture makers." Inspired by Rejlander, of whom he was a contemporary, Robinson will perhaps be best remembered by his earlier advocacy of combination printing. As early as 1855 Berwick and Anan exhibited a photograph which was the result of printing from more than one negative, a figure from one plate being cunningly introduced into a landscape print from another. Then came from Rejlander "The Two Ways of Life," in which, with wonderful ingenuity, thirty different negatives were combined. Robinson followed, and between 1865 and 1867 exhibited numerous examples of combination-printing, one of the most popular and fairly typical examples being "Carolling" (see plate), which received a medal in the exhibition of the Royal Photographic Society in 1887.

Though in this combination-printing one may perhaps perceive the germ of incentive towards the production of special effects not seen in the original, yet the practice was not destined to become very popular, for even in the most capable hands there remains the difficulty, if not impossibility, of fitting a portion of one negative into a print from another and still preserving true relative quality, and, even the proportion, if skilfully produced, eminently popular in character though "Carolling" may be, such errors are not absent. Of this combination-printing Dr P. H. Emerson has said: "Cloud printing is the simplest form of combination-printing, and the only one admissible when we are considering artistic work. Rejlander, however, in the early days of photography, tried to make pictures by combination-printing. This process is really what many of us practised in the nursery, that is, cutting out figures and pasting them into white spaces left for that purpose in the picture-book. With all the care in the world the very best artist living could not do this satisfactorily. Nature is so subtle that it is impossible to do this sort of patchwork and represent her. Even if the greatest truths be registered, the lesser truths, still important, cannot be obtained, and the softness of outline is easily lost. The relation of the figure to the landscape can never be truly represented in this manner, for all subtle modelling of the contour of the figure is lost."

Pictorial photography received a large accession of votaries in consequence of the greater facilities offered by the introduction of the gelatino-bromide, or dry-plate, process, which, although dating from 1880, did not notably affect photographic communities until some years afterwards; and although improvement in appliances and instruments had little to do with the advance of the pictorial side of photography, yet, indirectly at least, the dry-plate and the platinotype printing process have had an undoubted effect. The former gave enormously increased facility, and dispensed with tedious manipulations and chemical knowledge, while its increased light-sensitiveness decreased the limitations as to subjects and effects. The platinotype process was discovered in 1874-1880 by W. Willis, who employed his chemical skill and knowledge to give the world a printing process more likely than the hitherto prevalent silver papers to satisfy artistic requirements.

Up to 1882 but few outdoor photographers had ventured to run counter to the general dictum that photographs should only be taken during sunshine or good bright light, and unquestioning...
PHOTOGRAPHY

(continued from previous page)

Aroused into greater activity by these events, the Royal Photographic Society began to pay more attention to what had now become the more popular phase. At subsequent exhibitions the technical and scientific work was hung separately from the "Art Section," and a separate set of judges was elected for each section. It became the custom to allot by far the greater amount of space to the "artistic"; and later, artists were elected as judges, by way of encouraging those who were devoted to the pictorial side to send in for exhibition. In the autumn of 1900 the New Gallery was secured, and a comprehensive exhibition of all phases of photography was held.

It is interesting to note that as a distinct movement pictorial photography is essentially an offshoot of British origin, and this is shown by the manner in which organized photographic bodies in Vienna, Brussels, Paris, St. Petersburg, Florence and other European cities, as well as in Philadelphia, Chicago, &c., following the example of London, held exhibitions on exactly similar lines to those of the London Photographic Salon, and invited known British exhibitors to contribute. The international character of the "Linked Ring" encouraged an interchange of works between British and foreign exhibitors, with the result that the productions of certain French, Austrian and American photographers are perfectly familiar in Great Britain. This, in the year 1903, led to a remarkable cult calling itself "The New American School," which had a powerful influence on contemporaries in Great Britain.

It may be well to glance at such improvements of process or apparatus as have not been direct and essential means to pictorial advance, but rather modifications and improvements made in response to the requirements of the artistic aspirant. Such improvements present a score of two orders—those which are designed with the aim of securing greater accuracy of delineation, the correction of distortion and of apparent exaggeration of perspective, and the more truthful rendering of relative values and tones; and those which may not give this greater degree of pictorial finish, but have introduced improvements of an uncorrected objective, or even to dispense with the lens altogether, choosing rather to employ a minute aperture, technically called a "pinhole." This is but one example of many which might be quoted to bear out the statement that in photography the advance of anything in the nature of artistic qualities has not been correlated with mechanical improvements. The hand camera can be said to have had an influence on art, while photography preceded it; the photograph, and by removing the encumbrance of heavy tools has widened his sphere of operations; but it is perhaps in connexion with the plates and printing processes that more direct advantages have been derived from the pictorial point of view. The fact that the propor- tional to their luminosity was long regretted as an obstacle to correct representation; but by the introduction of orthochromatic or electrophotographic plates in 1886 (when B. J. Edwards bought the Taylor and Cleaver plates), and by the introduction of orthochromatic or electrophotographic plates in 1886 (when B. J. Edwards bought the Taylor and Cleaver plates), this original disability was removed; while with increased rapidity in the orthochromatic plate colour values may still further be corrected by the use of coloured screens or light filters, without interfering with the practicality of making sufficiently rapid exposures for most subjects. Again, by a better knowledge of what is required in artistic representation, certain improvements in the formulated treatment of ordinary plates and corrected plates are found to do much towards removing the evil; hence, with an ordinary plate "backed" so as to counteract over- exposure of the higher lights, an exposure may, except in extreme cases, be given of higher degree than that required to produce less actinic colours, and by subsequent suitable development a result hardly distinguishable from that of a colour corrected plate may be secured. Chemical experiment has placed in the photographer's hands improved and easier means of entire, unequal and local intensification and reduction, but utility of these is restricted. By the artistic worker it is claimed that the lens and camera are for the tools, and the negative the preliminary sketch or study, the form being standardized, and the pictorializing or painting does to the artist. In the production of the print various means of personally controlling the formation of the image have been resorted to. Two methods of development of platetype by means of glycine has its champions, but of greater little used, its resuscitation being chiefly due to two or three prominent workers in New York. Here should also be mentioned the revival in 1898 of rothemuth, or printing papers, whereby the sensitized with silver, the roughest texture drawing papers being employed to break up the excessive sharpness of the photographic image, and by the superficial inequalities introducing the effect
PHOTOGRAPHY, CELESTIAL

The requisites for celestial photography are best explained by a comparison with ordinary photography in several essential points.

a. Illumination.—In taking a portrait artificial light is used, being thrown on to the face of the sitter either directly or by reflection. If the day is dull a longer exposure is required, and artificial light may be used when the daylight fails. In photographing the stars there is no question of illuminating them by artificial light; for the strongest searchlight which we could throw in the direction of the heavenly bodies would have no sensible effect. The light used is their own, and its feebleness renders it necessary to take as long an exposure as possible, as we attempt to give images of fainter objects. The invention of the dry plate, by making it possible to give very long exposures, caused a revolution in celestial photography. With the wet plate, exposures were limited to the few minutes during which the film would remain wet; but the dry plate can remain in the telescope for days, weeks or even years if necessary. On the approach of daylight, the cap is put on the camera, or the plate removed into the dark room; but when night returns the plate is put back in the telescope, which is accurately pointed to the same stars, the cap is removed, and the exposure is resumed without any loss from the interruption.

b. Magnification.—In taking a portrait we can obtain a large or small size by placing the camera near the sitter or far away. But this method is not available for the heavenly bodies, since we cannot sensibly approach them. To magnify an image we must lengthen the focus of the camera, either directly or indirectly. The direct method is to construct a lens or mirror of long focus; the camera becomes similar in length to a telescope; and indeed resembles a telescope in other respects, except that we take away the eye-piece and put in a photographic plate instead. If, however, we already have a lens of short focus which we wish to use, we may lengthen the focus indirectly by using a secondary magnifier, that is by putting in another lens near the focus of the first. In either case the profitable magnification

is limited, not only by the imperfections of the optical apparatus but by disturbances in the atmosphere. Air currents, either outside or inside the telescope, act as irregular lenses of varying shape, and produce such defects in the image that we gain nothing by enlarging it beyond a certain point. Such air disturbances do not trouble the ordinary photographer at all, or scarcely at all: he is only concerned with a few feet of air, whereas the celestial photographer cannot escape from the necessity of looking through many miles of it.

c. Steadiness.—In taking a portrait the photographer is only concerned to fix his camera firmly and to induce his sitter to remain still. The heavenly bodies are in constant motion, though their real and apparent movements are fortunately smooth, except for air disturbances above mentioned. If, therefore, it were possible to devise perfectly smooth clockwork, we could keep the camera or telescope continually pointed to the required star or stars. But human workmanship has not yet made clockwork of sufficient strength and accuracy to keep a large telescope satisfactorily pointed. The clockwork which had been found good enough for use with visual telescopes was soon found to be quite inadequate for photography. The first method adopted was to bind two telescopes, one visual and the other photographic, firmly together; and by looking through the visual telescope and photographing with the other, we could make the motion with the screws; meanwhile the other telescope was kept properly pointed for taking a photograph. As it was sometimes found that extremely fine movements were required, electrical arrangements were devised, whereby the observer, on simply pressing a button, could accelerate or retard the rate of the clockwork by a minute amount, instead of actually turning the screws by hand. And about the same time the idea arose of making these corrections automatically. This automatic correction is based on the principle that a freely swinging pendulum, which has no work to do, will naturally keep much better time than if clockwork which has to drive a heavy telescope; and if such a pendulum is therefore arranged to send a current every second through certain electro-magnets, apparatus can be devised to detect whether the clockwork is going properly; and to correct it in the right direction, if it is not. One or more of these three methods, which may be called hand-guiding, electrical control, and automatic electric control, are used in taking all celestial photographs.

The Photographic Image.—The image of a star on the plate should be, theoretically, merely a point; but in practice it is a small patch on the plate which grows in size as the exposure is lengthened, while at the same time it becomes darker in the center. The reason is that light is many-colored, and when we attempt to focus it, by clockwork which has to drive a heavy telescope; and if such a pendulum is therefore arranged to send a current every second through certain electro-magnets, apparatus can be devised to detect whether the clockwork is going properly; and to correct it in the right direction, if it is not. One or more of these three methods, which may be called hand-guiding, electrical control, and automatic electric control, are used in taking all celestial photographs.

The Photographic Image.—The image of a star on the plate should be, theoretically, merely a point; but in practice it is a small patch on the plate which grows in size as the exposure is lengthened, while at the same time it becomes darker in the center. The reason is that light is many-colored, and when we attempt to focus it, by clockwork which has to drive a heavy telescope; and if such a pendulum is therefore arranged to send a current every second through certain electro-magnets, apparatus can be devised to detect whether the clockwork is going properly; and to correct it in the right direction, if it is not. One or more of these three methods, which may be called hand-guiding, electrical control, and automatic electric control, are used in taking all celestial photographs.
produced is magnified, it is seen to have a shape like that of a kite. As the exposure is prolonged the small kite-shaped figure gradually increases in size from the point towards the head, and this defect is the more pronounced the farther we depart from the centre of the plate. The result is, speaking generally, that the images near the centre of a plate may be fairly small and circular, but at a certain distance from the centre they become distorted and large. It is a practical problem of great importance to have this distance as great as possible, so that the field of good definition may be large. Estimating in terms of angular distance from the centre of the field, the reflecting telescope has a good field of not more than 40°; a telescope with one compound lens (the ordinary refractor) a field of about 1°, while if two compound lenses are used (as is the case in portrait photography) the field may be greatly extended, 10° or 15° having been successfully covered. This is naturally a very great advantage of the "doublet" over other forms of telescope, an advantage which has only recently been fully realized. But there is a compensating drawback; to get a large field we must either use a large plate, which is liable to bend or to have a permanent curvature; or if we use a small plate the picture will be on a small scale, so that we lose accuracy in another way.

**Star Charts** may therefore be made by photography with any desired combination of these advantages. The Cape Photographic Durchmusterung is a photographic survey of the southern hemisphere by means of 250 plates each covering 5° x 5° taken at the Royal Observatory, Cape of Good Hope; the plates being afterwards measured at Groningen in Holland by Professor J. C. Kapteyn who recorded the places to O°1 and O°1. A much higher degree of accuracy is aimed at in the international scheme for a map of the whole sky undertaken jointly by eighteen observatories in 1887. The plates are only 2° x 2°, and each of the eight observatories must take about 600 to cover its zone of the sky once, 1200 to cover it twice. Exposures of 6 min. 30 sec. and more, and a given, the telescope being pointed in a slightly different direction for each exposure; so that each star to about the 9th magnitude shows 3 images, and stars to the 11th or 12th magnitude show 2; which has the incidental advantage of distinguishing stars from dust-specks. A réseau of lines accurately ruled at distances of 5 mm. apart in two directions at right angles is impressed on the plate by artificial light and developed along with the star images; and by use of these reference lines the places of all stars shown with 3 min. exposure are measured with a probable error which, by a resolution of the executive committee, is not to exceed ± 0°02. An additional scheme of combination of these plates, which has been in operation with much longer exposure has proved too costly, and only a few observatories have attempted it. Meanwhile Professor E. C. Pickering of Harvard, by using doublet lenses which cover a much larger field at once, has photographed the whole sky many times over. The plates have not been measured, and would not in any case yield results of quite the same accuracy as those of the international scheme; but being systematically stored at the Harvard Observatory they form an invaluable reference library, from which the history of remarkable objects can be read backwards when once attention is drawn to them. Thus the history of the asteroid Eros, discovered in 1808, was traced back to 1894 from these plates; new stars have been found on plates 6 months previous to the time of discovery, and the epoch of their blazings up recovered within narrow limits; and the history of many variable stars greatly extended. The value of this collection of photographs will steadily increase with time and growth.

**Spectroscopic Star Charts.**—By placing a glass prism in front of the object glass of a telescope the light from each star can be extended into a spectrum: and a chart can thus be obtained showing not only the relative positions, but the character of the light of the stars. This method has been used with great effect at Harvard: and from inspection of the plates many discoveries have been made, notably those of several novae.

**The Geometry of the Star Chart.**—Let OS be the figure of the plate glass with which the photograph is taken, and let its optical centre be C. Let PL be the plate, and draw CN perpendicular to the surface of the plate. The point N is of fundamental importance in the geometry of the star chart and it is natural to call it the plate centre; whereby all place be measured from two other points which should theoretically, but may not in practice, coincide with it. The first is the line of the plate centre, as placed in position in the telescope. In the figure NL is purposely drawn larger than FN, and this is intended to show the fundamental shape of the right of N. The second point is that where the optical axis of the object glass (CG in the figure) cuts the plate. The object glass is placed on an exagated tilt so that CG falls to the right of CN. To secure adjustment, the object glass should be "looked on" to the tube by a familiar operation, so that the tube is parallel to CG; and then the plate should be set normal to the tube, and therefore to CG. This is done by observing reflected images, combined with rotation of the plate in its plane. The fact of the object glass will in general be curved: so that the points of best focus for different stars lie on a surface such as AGB (purposely exaggerated). The best practical results for focus will thus be obtained by compromise, placing the plate so that the stars, as a whole, lie on the plate, and others, like B, nearer the object glass: exact focus only being possible for a particular ring on the plate. The star A will thus be represented by a small patch of light, on the plate, which will grow in size as aberration increases. When we know the position of its image we select the centre as best we can; and in practice it is important that the point selected should be that where the line CA drawn from the star to the optical centre cuts the plate. If this can be done, the chart represents the actual projection of the heavens from the point O on to the plane PL. The stars are usually conceived as lying on the celestial sphere, with an arbitrary radius and centre at the observer, which is in this case the object glass: describing such a sphere with C as centre and CN as radius, the lines KCB and eCA project the spherical surface on to a tangent plane at the point N, which we call the plate centre. If we point the telescope to a different part of the sky we select a different tangent plane on which to project. It is a fundamental property of projections that a straight line projects into a straight line; and in the present instance we may add that every straight line corresponds to a great circle on the celestial sphere. Hence if we measure any rectilinear co-ordinates (x, y) of a series of stars on one plate, and co-ordinates (X, Y) of the same stars on another plate, and (x, y) are connected by a linear relation, so must (X, Y). This property leads at once to the equation

\[ X = (a + by + cy)/(1 - kx - ly), \]

(1)

the numerators being any linear functions of (x, y) but the denominators being the same linear function. When \( x = 0 \), \( y = 0 \), then \( X = c \) and \( Y = f \), which are just the co-ordinates of the origin of (xy) on plate (X, Y) can be shown to be \((k, l)\) if proper units of length are chosen.

As a particular case the co-ordinates

\[ x = \cot \delta \cos \alpha, \quad y = \tan \delta \sin \alpha \]

(2)

represent the rectangular co-ordinates of a star RA and declination \( \delta \), projected on the tangent plane at the north pole. If the same star be projected on the tangent plane at the point (A, D), then its rectangular co-ordinates \((\xi, \eta)\) will be

\[ \xi = \tan (a - A) \sin \phi \sec (D - \gamma), \quad \eta = \tan (D - \gamma), \]

(3)

where \( \tan \phi = \tan \delta \sec (a - A) \),

the axis of \( x \) being directed towards the pole. It can readily be verified that the (xy) co-ordinates are given by relations of the form (1). The co-ordinates \((\xi, \eta)\) have been named "standard co-ordinates" and represent star positions on an ideal plate free from the effects of perspective on and aberration with plates of not too large a field, differential refraction and aberration are so small that their product by squares of the co-ordinates may be neglected, and the actual star positions \((x, y)\) are connected with \((\xi, \eta)\) by linear relations. The accessibility of these co-ordinates is obviously not disturbed by the choice of origin of axes and of orientation; in which the effects of precession and mutation for any epoch may be included. Hence to obtain the standard co-ordinates \((\xi, \eta)\) of any object on a plate it is necessary to know its position in the plate centre (the point N in fig. 1) and the six constants in the relations

\[ x = Ax + By + C, \quad y = Dx + Ey + F, \]

(4)

where \((x, y)\) are rectilinear co-ordinates referred to any axes. The constants can theoretically be determined when there are three stars on the plate for which \(x, y\) are known; but in practice it is better to use as many \(\text{known}^\star\) stars as possible. These equations

\[ 2, 3, 5 \]

PHOTOMETRY

are well adapted to solution by least squares or any equivalent device.

Photography of Nebulae and Clusters.—Some of the earliest and most striking successes in celestial photography were the pictures of nebulae. Dr. A. A. Common (1841–1909), F. R. S., of Kew, after a tour in 1883 with a successful picture of the great nebula in Orion, taken with a 3 ft. concave mirror by Calver. Dr Israel Roberts (1829–1902) was the first to show the real structure of the great nebula in Andromeda, by a photograph also taken with a reflector. In the clear atmosphere of the Lick Observatory in California, small nebulae were photographed in great numbers by Professor J. E. Keeler (1857–1900); and it was shown what a large percentage were spiral in form. Prof. G. W. Ritchey, at the Yerkes Observatory, has followed up these successes with a 4-ft. reflector, and is constructing a 5-ft., to be erected on Mt Wilson (Cal.); but he has also shown that pictures of clusters are best taken with a telescope of long focus, such as the great Yerkes refractor; and incidentally that this telescope, although intended for visual work, can be adapted to photography by using a "colour screen" just in front of the plate, which sifts out the rays not brought to focus.

Photography of the Moon.—G. W. Ritchey has used the same device of a colour screen for the moon, and obtained even better pictures than those obtained at Paris, which were previously the best. The positions of a large number of craters and other points have been measured by Dr J. H. G. Franz and S. A. Saunders on photographs, and a new epoch in lunar topography has thereby been created.

Photography of the Planets.—Some striking successes have been obtained at the Lowell Observatory, Flagstaff, Arizona: by cutting down the aperture of the object-glass some of the delicate markings, called canals, on the planet Mars have been photographed; but even these do not approach what can be seen by the eye.

Photography of Comets.—Some wonderful pictures have been obtained of comets by Professor E. E. Barnard and others. Here, as in the case of nebulae, the photograph is superior to the eye in detecting faint luminosity, and delicate details of the tail structure have been photographed which could never be seen. In several pictures the tails have an appearance of violent shattering, and if successive pictures can be obtained at such times we may learn something of the nature of such disturbances.

Solar Photography.—The light of the sun is so intense that the chief difficulty is to obtain a short enough exposure. When successfully taken, photographs of the surface show the well-known spots and the motting of the surface. The image sensibly falls off in intensity towards the limb, owing to the absorption of light by the solar atmosphere; and the bright faculae (which are thus inferred to lie above the main absorbing layer) are seen near the limb. But an immense advance in solar photography was made about a dozen years ago by the invention of the spectroheliograph, which is an instrument for photographing in the light of one very definite colour—say a single hydrogen line. The faculæ appearances can be photographed with this instrument all over the sun's disk, instead of merely near the limb. The appearance presented varies enormously with the line selected, or (in the case of the wide "lines" in the spectrum, such as the H and K lines) with the particular part of the same line selected. But for a full account of such matters reference must be made to the articles SUN and SPECTROHELIOGRAfH.

AUTHORS.—Various papers in the Monthly Notices of the Royal Astronomical Society and in the Astrophysical Journal. Also the bulletins and circulars of the Harvard, Lick and Yerkes Observatories; and of the Executive Committee for the Astrophographic Catalogue (published by Gauthier Villars for the Paris Academy des Sciences). See also a most especially a paper by G. W. Ritchey in the Decennial Papers of the University of Chicago, reprinted in vol. ii. (1903) of the Yerkes Observatory Publications. (H. T. H.)

PHOTOMETRY (from Gr. φωτός, φωτεῖνα, light, μέτρηνα, a measure), the art and science of comparing the intensities or illuminating powers of two or more sources of light. As in all scientific measurements, its methods are attempts to give quantitative accuracy to the crude comparisons made by the eye itself. The necessity for this accuracy in practical affairs of life has arisen because of the great development of artificial lighting in recent times. The eye soon learns to associate with any particular source of light a quality of brightness or power of illumination which diminishes with increase of distance from the source or from the surface illuminated. This quality depends upon an intrinsic property of the source of light itself, generally known as its "candle power." The aim of photometry is to measure this candle power; and whatever be the experimental means adopted the eye must in all cases be the final judge.

In the photometric comparison of artificial lights, which frequently vary both in size and colour, direct observation of the sources themselves does not yield satisfactory results. It is found to be much better to compare the illuminations produced on dead white surfaces from which no regular reflection takes place, or through colourless translucent material uniformly illuminated by the light placed on the further side. By such processes there is always loss of light, and we must be certain that the various coloured constituents of the light are reduced in the same proportion. This necessary condition is practically satisfied by the use of white diffusing screens.

Two principles of radiation underlie many photometric applications, namely, the inverse square distance law, and J. H. Lambert's "cosine law." Both can be established on theoretical grounds, certain conditions being fulfilled. But as these conditions are never absolutely fulfilled, the applicability of the two laws must in the end be tested by experiment. Since we find that within the errors of observation four candles, placed together at a distance of 2 ft. from a diffusing screen, produce the same illumination as one candle at a distance of 1 ft., we may regard the inverse square distance law as satisfied. Thus if two lights of intensities A and B produce equal illuminations on a screen when their distances from the screen are respectively a and b, we at once write down the relation between the two intensities in the form A : B = a² : b². The theoretical basis of the law follows at once from the universally accepted view that light is energy radiating outwards in all directions from the source. If we assume that there is no loss of energy in the transmitting medium, then the whole amount of radiant energy passing in one second across any closed surface completely surrounding the source of light must be the same whatever the size or form of the surface. Imagine for simplicity a point source of light; or its equivalent, a uniformly radiating spherical surface with the point at its centre, and draw round this point a spherical surface of unit radius. Across this surface there will pass a definite amount of radiant energy, in other words a definite total luminous flux, E, which will be the same for all concentric spherical surfaces. Since the area of a spherical surface of radius r is 4πr², the flux which crosses unit area is E/4πr². This quantity is called the "illumination." It is measured in terms of the unit called the lux, which is defined as the illumination produced by a light of unit intensity on a perfectly white surface at a distance of 1 ft. In the great majority of photometers the illuminations are compared, and the intensities are deduced by applying the law of the squared distances.

Lambert's cosine law has to do with the way in which a luminous surface sends off its radiations in various directions. It is a matter of common observation that the disk of the sun appears equally bright all over the surface. Careful measurements show that this is not strictly true; but sufficiently near the truth to suggest that under certain definable conditions the law would hold accurately. Again, when a glowing surface is viewed through a small hole in an opaque plate, the brightness is very approximately independent of the angular position of the incandescent surface. This is the same phenomenon as the first mentioned, and shows that the more oblique, and therefore larger, element of surface sends the same amount of radiation through the hole. Hence the amount per unit surface sent off
at a given angle with the normal must be less than that sent off in the direction of the normal in the inverse ratio of the areas of the corresponding normal and oblique elements; that is, as the cosine of the given angle to unity. For most practical purposes, and so long as the obliquity is not great, Lambert's law may be assumed to hold.

In almost all accurate methods of photometry the aim is to bring the illuminating powers of the two sources to equality. This may be effected by altering the distance of either light from the illuminated surface. Or we may use polarized light and diminish the intensity of the stronger beam by suitable rotation of a Nicol prism, a method particularly useful in spectrophotometers. The same result may also be effected by interposing absorbing disks, the precise absorbing powers of which must, however, be known with great accuracy. Another useful method is that first described by H. Fox Talbot in 1834, and used with effect by Professor William Swan (1849), and more recently by Sir W. de W. Abney.

Talbot's Law.

Talbot's law is thus enunciated by H. von Helmholtz: "When any part of the retina is excited by regularly periodic intermittent light, and when the period is sufficiently short, the resulting impression will be continuous, and will be the same as that which would be produced if the whole light were distributed uniformly throughout the whole period." Talbot deduced the principle from the well-known experiment in which a continuous luminous line is produced by rapid rotation of a luminous point. If the principle be granted, it is obvious that any mechanism by which a ray of light is obstructed in a regularly rhythmic manner during definite intervals $t$, separated by intervals $t'$, during which the light is allowed to pass, will have the effect of reducing the apparent brightness of the ray in the ratio $t/(t + t')$. This is frequently accomplished by placing in the ray a rotating disk perforated by radial sectors, the so-called Talbot disk.

If photometric results are to be of general value it is essential to have a unit in which to express all other intensities. For example, electric lights are classified according to their "candle-power." The candle, in terms of whose brightness the brightness of other sources of light is to be expressed, must, of course, fulfill the conditions demanded of all standards. It must give under definite and constant conditions a definite constant luminous effect, and it must be easily reproducible. The earlier attempts to get a candle of constant brightness were not very satisfactory. The British standard is a sperm candle which weighs $\frac{1}{12}$ lb, and loses in burning 120 grains per hour. It is found that these conditions are not sufficient to determine the luminous power of the candle, since the length and shape of the wick, the height of the flame, and the composition, temperature and humidity of the atmosphere all have an effect upon its brightness. The same is true of other similar sources of light—for example, the German standard candle, which is made of paraffin, has a diameter of 2 cm., and has its wick cut until the flame is 5 cm. high, but which with all precautions suffers continual alteration in brightness. For ordinary practical purposes, however, these candles are nearly enough. Other kinds of flame have also been used as a standard source of light. The oldest of these is the French Carcel lamp, which is provided with a cylindrical Argand burner, and gives the standard brightness when 42 grammes of colza oil are consumed per hour. The supply and draught are regulated by clockwork.

Vernon-Harcourt Pentane Standard.

A. G. Vernon-Harcourt's pentane standard, in which a mixture of gaseous pentane and air is burnt so as to maintain a flame 2.5 in. high at ordinary barometric pressure, gives good results. With proper care it is an instrument well adapted to all purposes. Several forms of this standard have been constructed; one of the most important being the 10-candle-power pentane lamp, in which air saturated with pentane vapor is burnt in a specially-designed burner resembling an Argand burner. For photometric purposes a definite length of the lower part of the flame is used, the upper part being hidden within an opaque tube. The amyl-acetate lamp designed by H. von Hefner-Altenbeck has been elaborately studied by the German authorities, and at present is probably more used than any other flame for photometry. It is of simple construction, and gives the standard brightness when it burns with a flame 4 cm. high, and is in still air of uniform 0-88% and free from carbon dioxide. The presence of carbon dioxide and increase in the humidity have a marked effect in diminishing the brilliancy of the flame. If the vapour pressure is $e$ and the barometric pressure $p$, the strength of the flame, when all other conditions are fulfilled, is given by the formula

$$I = \frac{940}{e} \cdot \frac{5}{p-e}$$

One disadvantage for photometric purposes is the reddish color of the flame as compared with the whiter artificial lights in general use.

For an interesting account of the various experimental investigations into the properties of the Hefner flame see E. L. Nichols, "Standards of Light," Transactions of the International Electrical Congress, vol. ii. (St Louis, 1904). Angstrom's determination of the radiation of the flame in absolute energy units is also of special interest.

Attempts have been made, but hitherto with limited success, to construct a convenient standard with acetylene flame. Could a satisfactory burner be devised, so that a steady brilliancy could be easily maintained, acetylene would, because of its intense white light, soon displace all other flames as standards.

J. Viole has proposed to use as standard the light emitted by a square centimetre of surface of platinum at its melting-point, but there are obvious practical difficulties in the way of realizing this suggested standard. J. E. Viole's Platinum Standards. Petavel, who carefully examined the necessary conditions for producing it (Proc. Roy. Soc. 1899), finds that the platinum must be chemically pure, that the crucible must be made of pure lime, that the fusion must be by means of the oxy-hydrogen blow-pipe, that the gases must be thoroughly mixed in the proportion of 4 volumes of hydrogen to 3 of oxygen, and that the hydrogen must contain no hydro-carbons. Under these conditions the variation in the light emitted by the molten platinum would probably not exceed 1%. O. Lummner and F. Kurlbaum have proposed as a standard a strip of platinum foil 25 mm. wide and .015 mm. thick brought to incandescence by an electric current of about 80 amperes. The temperature of the strip is 2500° C. The intense light is transmitted through a water trough 2 cm. in width. This ratio is determined by means of a bolometer, and so long as it is adjusted to $\frac{1}{4}$th the light is practically constant.

For comparative photometric work the incandescent electric light is very convenient, having the one great advantage over candles and flames that it is not affected by atmospheric changes. But it does not satisfy the requirements of a primary standard. It ages with use, and when run at constant voltage gradually loses in brilliancy, partly because of changes in the filament itself, partly because of the deposit of carbon on the interior of the bulb. Professor J. A. Fleming has shown that very good results can be obtained if carbon filaments carefully selected and run in ordinary bulbs for a definite time at a little above their normal voltage are remounted in large clear glass bulbs 6 or 8 in. in diameter.

Fleming's Incandescent Lamp Standard.

If used sparingly, and never above their marked voltage, these large incandescent bulbs have been found to remain constant for years, and therefore to be eminently suitable as secondary standards. In his Handbook for the Electrical Laboratory and Testing Room (vol. ii.) Fleming concludes that the best primary standards are the Viole incandescent platinum and the Vernon-Harcourt pentane one-candle flame; and that the most convenient practical standards are the Hefner lamp, the ten-candle pentane lamp, and the incandescent electric lamp. Comparisons of the intensities of these various standards do not give quite concordant results. Thus three different authorities have estimated the 10-candle pentane lamp as being equal to 10-75, 11-0, 11-4 Hefner lamps.

A specially constructed instrument or piece of apparatus for comparing light intensities or illuminations is called a
photometer. The earlier forms of photometers were very simple
and not capable of giving very precise results. The principles of
construction are, however, the same in all the recog-
nized forms down to the most elaborate of recent
inventions. Two of the earliest forms were described
by P. Bouger and W. Ritchie. The Ritchie wedge constitutes
the basis of many varieties of type. The two lights to be
compared illuminate the sides of the two lightness
is placed between them, so that the eye set in front of
the wedge sees the two sides illuminated each by one
of the lights. The edge should be as sharp as possible so that
the two illuminated surfaces are in close contact. The
illuminations are made equal either by shifting the wedge along the line
joining the lights or by moving one of the lights nearer to or
farther from the wedge as may be required. The lights given
out by the sources are then as the squares of the distances from
the matched parts of the surfaces. Count Rumford
suggested the comparison of the intensity of the
shadows of the same object thrown side by side on
a screen by two lights to be compared. In this case
the shadow due to one source is lit up by the other alone;
and here again the amounts of light given out by the sources
are as the squares of their distances from the screen when
the shadows are equally intense. The shadow-casting object
should be near the screen, so as to avoid penumbras as much as
possible; yet not too near, so that the shadows may not
overlap.

R. Bunsen suggested the very simple expedient of making
a grease-spot on white paper for photometric purposes. When
the paper is equally illuminated from both sides the
grease-spot cannot be seen except by very
close inspection. In using this photometer, the
sources are placed in one line with the grease-spot, which lies
between them and can be moved towards one or other. To
make the most accurate determinations with this arrangement
the adjustment should first be made from the side on which
one source lies, then the screen turned round and the adjust-
ment made from the side of the other source—in both cases,
therefore, from the same side of the paper screen. Take
the mean of these positions (which are usually very close together),
and the amounts of light are as the squares of the distances
of the sources from this point. The efficiency of this
photometer has been improved by using two inclined mirrors
so that the eye views both sides of the paper simultaneously.

Sir Charles Wheatstone suggested a hollow glass bead, silvered
internally, and made to describe a rapid closed path, for
use as a photometer. When it is placed between two
sources we see two parallel curves of reflected light,
one due to each source. Make these, by trial, equally
bright; and the amounts of light from the sources are
again, as the squares of the distances.

William Swan’s prism photometer, invented in 1859, is a useful
application of the principle embodied in Bunsen’s grease-spot photo-
meter (see Trans. Roy. Soc. Ed. vol. xxii). The essential
part of the instrument is fundamentally the same as
that described by O. Lumm er and E. Brod h un in 1889.

It consists of two equal right-angled isoclines glass
prisms placed with their diagonal faces together so as to form a cube
(fig. 1), and cemented together by a small patch of Canada balsam,
which spreads out into a circle when the prisms are pressed to-
gether. In the figure, which represents a central section of the
bi-prism, the Canada balsam is represented by the letter N. The
light from two illuminated sur-
faces, PQ, RS, is allowed to fall
upon the portion backed by the
Canada balsam is almost wholly
transmitted. Thus an eye placed
in the position q p receives light from both sources, the surface
RS supplying nearly all the light that seems to come from the patch
PQ and the surface PQ supplied by all the light that seems to
come from the region immediately surrounding N. The patch N
will in general be visible; but it will quite disappear when the
luminosity of the ray PT, which traverses the Canada balsam, is
exactly equal to the luminosity of the ray RN, which has been
after total reflection from the surface PQ.
This condition of invisibility of N is arrived at by adjusting the positions of the
light with illuminated surfaces PQ, RS. The brightnesses of the two sources will then be as the squares of their distances from their respective screens.

The essential part of Lumm er and Bro d h un’s photometer is a combination of prisms very similar to Swan’s. In its most im-
proved form the bi-prism or ‘optical cube’ has one
Lumm er and Bro d h un’s
Photometer.

For this purpose, two
of the component prisms cut in a peculiar manner.
The diagonal face is partly cut away, so that the central
section of this face can be let into the diagonal face of the other prism.
The Canada balsam is dispensed with, the surfaces being pressed closely together so that the axes of light are between the
faces, and become the parts through which light is freely transmitted. On
the other hand, the light which enters the second prism and falls on the
surfaces of the prism backed by air is transmitted so far that
the cut-out parts is totally reflected. The general result is the pro-
duction of two similar luminous patches l and r, each of which
is surrounded by a field of the same intensity as the other patch.
When the photometric match is made the whole region will be
uniformly bright. But, by insertion of strips of glass so as to
weaken equally the intensity in the surrounding fields, the
match will be obtained when these fields are made of equal intensity and the
same as the patch of light from the sources is reflected back to
them. Under these conditions the eye is able to judge more
certainly as to the equality of intensity of the two patches, and an
untrained observer is able to effect a comparison with an accuracy
which is impossible with most forms of photometer.

J. Joly’s diffusing photometer consists of two equal rectangular
parallelepipeds of a translucent substance like paraffin separated
by a thin opaque plate. It is set between the source by reflec-
tion from symmetrically situated mirrors so as to enter the sides
AB and AD perpendicularly. An important modification, due
also to Lumm er and Bro d h un, is the following: By means of a
photometric wedge, the portion RS are brought to be equal to the
half of the diagonal face of the one prism, and from the other half
of the same prism there is removed in like manner all but a part l
corresponding to the part r. The portion which have not been
removed are pressed closely to the diagonal face of the other prism,
and become the parts through which light is freely transmitted.
On the other hand, the light which enters the second prism and falls on the
surfaces of the prism backed by air is transmitted so far that
the cut-out parts is totally reflected. The general result is the pro-
duction of two similar luminous patches l and r, each of which
is surrounded by a field of the same intensity as the other patch.
When the photometric match is made the whole region will be
uniformly bright. But, by insertion of strips of glass so as to
weaken equally the intensity in the surrounding fields, the
match will be obtained when these fields are made of equal intensity and the
same as the patch of light from the sources is reflected back to
them. Under these conditions the eye is able to judge more
certainly as to the equality of intensity of the two patches, and an
untrained observer is able to effect a comparison with an accuracy
which is impossible with most forms of photometer.
PHOTOMETRY

Measurement of as many rays as can be conveniently combined. One of the best methods of effecting this is by means of Matthew's C. P. Matthew's integrating photometer. By the integrating use of twelve mirrors arranged in a semicircle whose photometer, the diameter coincides with the axis of the lamp, twelve rays are caught and reflected outward to a second set of twelve mirrors which throw the rays on to the surface of a photometric screen. This combined effect is balanced by the illumination produced by a standard lamp on the other side of the screen (see Trans. Amer. Inst. Elect. Eng., 1902, vol. xix.).

So long as the lights to be compared are of the same or nearly the same tint, the photometric match obtained by different observers is practically the same. If, however, they are of distinctly different colours, not only do different observers obtain different results but those obtained by the same observer at different times are not always in agreement. Helmholtz was of opinion that photometric comparison of the intensities of different coloured lights possessed no real intrinsic value. There can be little doubt that in a rigorous sense this is true. Nevertheless it is possible under certain conditions to effect a comparison which has some practical value. For example, when the intensities of two differently coloured lights differ considerably there is no difficulty in judging which is the stronger. By making the one light pass through a fairly large range of brightness we may easily assign limits outside which the intensities are undoubtedly different. After some experience these limits get close; and many experimenters find it possible, by taking proper precautions, not only to effect a match, but to effect practically the same match at time after time. According to Abney, whose memoirs on colour photometry (Phil. Trans., 1886, 1892) form a most important contribution to the subject, the observer in making his judgment as to the equality of luminosity of two patches of colour placed side by side must not begin to think about it, but must let the eye act as unconsciously as possible. His method was to compare the coloured patch with white light given by a particular standard and cut down to the proper intensity by use of a Talbot's rotating sector, which could be adjusted by means of a suitable mechanism while it was rotating.

At the same time, although the eye may be able to effect a colour match for a pair of colours of a particular luminosity, it has been long known that a change in the luminosity will destroy the apparent equality. This depends upon a physiological property of the retina discovered by E. Purkinje in 1825 (see below, Celestial Photometry). In virtue of this property the eye in the blue and violet end of the spectrum is more stimulating to the eye than the red end when the general luminosity is low, whereas at high luminosities the red gains relatively in brightness until it becomes more stimulating than the blue. Unless therefore account is taken in some definite measurable manner of the absolute brightness, there must always be some uncertainty in the photometric comparison of the intensities of differently coloured sources of light.

Instead, however, of trying to effect a photometric match in any of the ways which have been found sufficient when the sources are of the same or nearly the same tint, we may effect important practical comparisons in what is called heterochromatic photometry by an appeal to other physiological properties of the eye. For example, the power of clearly discriminating patterns in differently coloured lights of various intensities is obviously of great practical importance; and this power of detailed discrimination may be made the basis of a method of photometry. According to this method two lights are arranged as to illuminate two exactly similar, but differently coloured, parts of the retina, for example, on the sides of a Ritchie wedge, and their distances are adjusted until the patterns are seen equally distinct on the two sides. Application of the usual distance law will then give the relation between the two lights. A discrimination photometer constructed on this principle has been designed by J. A. Fleming. Its results do not agree with the indications of an ordinary luminosity photometer; for it is found that the eye can discriminate detail better with yellow than with blue light of the same apparent luminous intensity.

Another and very promising method of photometry depends upon the duration of luminous impressions on the retina. J. A. Plateau observed in 1829 that the blending of a homogeneous impression of a pattern of alternate sectors of black and some other colour marked on a disk when that disk was rotated occurred for rates of rotation which depended on the colour used. A form of experiment suggested in Professor O. N. Rood's Modern Chromatics seems to have been first carried out by E. L. Nichols (Amer. Journ. of Science, 1881). A black disk with four narrow open sectors was rotated in front of the slit of a spectroscope. When the rotation was not too quick the yellow part of the spectrum appeared as a succession of flashes of light separated by intervals of darkness of appreciable length, whereas towards both red and violet ends no apparent interruption in the steady luminosity could be observed. As the rate of rotation increased the part of the spectrum in which flickering appeared contracted to a smaller length extending on each side of the yellow, and finally with sufficiently rapid alternation the yellow itself became steady. This seems to show that the retinal image persists for a shorter time with yellow light than with light of any other colour; for with it the intervals of darkness must be shorter before a continuous impression can be obtained. Now yellow is the most luminous part of the spectrum as it affects the normal human eye; and E. S. Ferry (Amer. Journ. of Science, 1892) has shown that the sensation of luminous impression is not, in fact, entirely determined by the luminosity of the ray. Hence the determination of the minimum rate of intermittence at which a particular colour of light becomes continuous may be regarded as a measure of the luminosity, the slower rate corresponding to the lower luminosity. Although in the experiment just described the red part of the ordinary solar spectrum becomes continuous for a slower rate of intermittence than the yellow part, yet we have simply to make a red ray as luminous as the yellow ray to find that they become continuous for the same rate of intermittence. It is, however, highly improbable that the duration of impression depends only on the luminosity of the light and not to some extent upon the wave-length. There are indeed phenomena which require for their explanation the assumption that the duration of luminous impression does depend on the colour as well as on the brightness.

Nevertheless the luminosity is far the more important factor, as shown by Ogden N. Rood's experiments. He found (Amer. Journ. of Science, 1893) that, when a disk whose halves differ in tint but not in luminosity is rotated rather slowly, the eye of the observer sees no flickering such as is at once apparent when the halves differ slightly in luminosity. Rood himself suggested various forms of photometer based on this principle. In his latest form (Amer. Journ. of Science, Sept. 1899) the differently coloured beams of light which are to be compared photometrically are made to illuminate the two surfaces of a Ritchie wedge set facing the eye. Between the wedge and the eye is placed a cylindrical concave lens, which can be set in oscillation by means of a motor in such a way that first the one illuminated surface of the wedge and then the other is presented to the eye in sufficiently rapid alternation. The one source of light is kept fixed, while the other is moved about until the sensation of flicker disappears. From work with this form of instrument Rood concluded that "the accuracy attainable with the flicker photometer, as at present constructed, and using light of different colours almost spectral in hue, is about the same as with ordinary photometers using light of white light, or light of exactly the same colour."

Various modifications of Rood's forms have been constructed from time to time by different experimenters. The Simmance and Abadby flicker photometer is an ingenious and yet mechanically simple method by which (as it were) the wedge itself is made to oscillate as to throw the eye in rapid succession first on the one side and then the other. The rim of a wheel of white material is bevelled
in a peculiar manner. The sharp edge, which passes slightly obliquely across the rim from one side of the wheel to the other and back again, is the meeting of two exactly similar and with it the lines of crossed and recrossed light, the one line being the line of vision during each revolution. Hence first the one illuminated side and then the other are presented to the eye in rapid alternation. The inventors of this instrument claim that their instrument can be discerned by the eye in a direction that the 
the near of different colour (Phil. Mag., 1904). There is no doubt that results obtained by the spectrophotometer are better agreement than with any other form of Nicol prism. The comparative ease with which the balance is obtained even when the tints are markedly different shows that its action depends upon a visual distinction which the eye can readily appreciate, and this distinction is mainly that of brightness.

The spectrophotometer is an instrument which enables us to make photometric comparisons between the similarly coloured spectra of the two different sources of light, or of two parts of the same original source after they have passed through different absorbing media. When it is desired to compare the intensities of the spectra from two different sources a convenient form is the one described by E. L. Nicholls. A direct vision spectroscope mounted upon a carriage travels along a track between the two sources. In front of the slit two right-angled triangular prisms are set so that the light from each source enters the side of one prism perpendicular and is totally reflected into the spectroscope. The two spectra are then seen side by side. Attention being fixed on some chosen narrow portion, say, in the green, the instrument is moved along the track between the sources until the two portions appear of the same intensity. The process is then repeated until the whole spectrum has been explored.

In Lummer and Brodhun's form of spectrophotometer the rays to be compared pass in perpendicular lines through the modified Swan double prism, and then together side by side through the Nicol prism. Suggestion in the form of the two prisms, Professor D. B. Brace (Phil. Mag., 1899) made the combined prism serve to produce the spectra as well as to effect the desired comparison. In this arrangement the compound prism ABC (fig. 2) is made up of two right-angled equal prisms whose longer sides are in contact, so that the whole forms an equilateral prism with three polished faces, the polished faces being silvered. Part of the interface AC is silvered, the silvering forming a narrow central strip running parallel to AB. Along the whole length of the interface the two prisms are cemented together with Canada balsam or other material having as nearly as possible the same refractive index as the glass. When two rays R, S enter symmetrically from opposite sides of the base of the compound prism as shown in the diagram, the ray R will pass through the prism except where the silver strip intercepts it, and will form a part of a spectrum visible to the eye placed at R, while the rays S, emerging in the same direction, will be dispersed into the two spectra from the silvered surface. Thus two systems of adjacent parallel rays of white light will form on emerging spectra with corresponding rays exactly parallel. With these and other forms of instrument the accuracy of the instrument itself is much increased, and the whole process of equal intensity by a method which enables him to compare the original intensities of the sources. In most cases the relative intensities of the portions of the spectra being compared cannot be conveniently altered by varying the intensity of the instrument, and the required comparison is therefore generally had to one of the other methods already mentioned, such as the use of polarizing prisms or of rotating sectors. Under certain conditions K. Vierordt's method of allowing the subject to see two images of the spectra, one each, and of varying the width of the two images, too great confidence cannot be placed upon it.

In other types of spectrophotometer, such as those associated with the names of H. Tränka, A. Crova, H. Wild, G. Hüfner, O. W. L. Mace, etc., the photometric comparison of two spectra is made by the eye alone. croca for example, in the König-Martens instrument the two rays which are to be compared enter the upper and lower halves of a divided slit. After passing through a lens they pass in succession through (1) a dispersing prism, (2) a Wollaston prism, (3) a binocular eyepiece, and (4) a Nicol prism. The two pairs of images of the original rays can be calculated. An important application of the spectrophotometer is to measure the absorptive powers and extinction coefficients of transparent substances for the two spectral regions. In the original form of the instrument the intensities of the reflected spectra are made equal—in other words, a match is established. In the process of the rays of one of the spectra the absorbent substance is then in turn introduced into the beam of the other. A measure of the loss of luminosity due to the interposition of the absorbent substance is thus obtained.

To facilitate experiments of this nature Dr. J. R. Milne has devised a spectrophotometer which presents some novelties of construction (see Proceedings of the Optical Convention, 1905, vol. 1). The light from a bright flame is suitably projected by a lens so as to illuminate a small hole in the end of the collimator. The rays from this point-source are made parallel by the collimator, and then pass, partly through the absorbing medium, partly through the space above it. These two beams converge on the opposite sides of the Nicol prism and then fall upon a screen with two parallel rectangular openings, the upper one allowing the unabsorbed part of the beam to pass, the lower part which has been transmitted through the absorbing medium. A spectroscope placed before the screen converges the rays suitably upon a Wollaston prism, so that two spectra are seen side by side, having their light polarized in perpendicular planes. A Nicol prism is placed between the two prisms and the eye-piece of the telescope, and by its rotation in the manner already described the intensities of any two corresponding portions of the two spectra can be brought to equality. Careful attention to all necessary details Milne shows that his instrument satisfies the requirements of a good spectrophotometer: for (1) the rays through the absorbing medium can be made strictly parallel; (2) the two spectra can be brought with ease accurately edge to edge; (3) any light spectrum of the eye can be transferred to the screen can be made conjugate to the retina of the observer's eye; (4) not only do the two spectra touch accurately along their common edge, but the two fans of rays which proceed from every point of the common edge lie in one and the same plane; (5) the eye is called upon to judge the relative intensities of not two narrow slits but of two broad uniformly illuminated areas. Milne also points out that this instrument can be used as a spectropolarimeter.

In all these methods, however, the results depend for their action upon the properties of polarized light which are necessarily open to serious objections, such as: selective absorption in the calcarpe, altering the relative intensities of the constituents in the original rays; selective losses by reflection of polarized rays at the various optical surfaces; and the necessarily imperfect performance of all forms of polarizing media. To eliminate these defects as far as possible great care in construction and arrangement is needed, otherwise corrections must be applied. It is evident that if the successive parts of the two spectra are compared photometrically we need, by a process of summation obtain a comparison of the total luminosities of the lights which form the spectra. This process is far too tedious to be of any practical value, but sufficiently accurate results may in certain cases be obtained by comparison of two or more particular parts of the spectra, for example, strips in the red, green, and blue. Similar in principle is the method suggested by J. Macé de Lépinay, which matches his lights by looking first through a red glass of a particular tint and then through a chosen green. If R and G represent the corresponding ratios of the intensities, the required comparison is calculated from the formula

$$ I = \frac{1 + o - 2o \delta (1 - GR)}{1 + o - 2o \delta (1 - GR)} $$

A. Crova, one of the earliest workers in this subject, effects the photometric comparison of differently coloured lights by matching those monochromatic rays from the two different which have the same intensities as the whole collected rays that make up the lights. Careful experiment alone can determine this particular ray, but were it once ascertained for the various sources of light in use the method would have the merits of rapidity and accuracy sufficient for...
PHOTOMETRY

practical needs. Spectrophotometric observations are necessary to
determine the position in the spectrum of the particular mono-
chromatic ray, but when it has been determined a coloured
glass may be more readily allowed in the neighbourhood of
this ray to pass, and the photometric comparison may then be
affected by looking through this glass.

This article has been confined strictly to the methods of visual
photometry, with very little reference to the results. Comparison
of intensities of radiation by photographic means or by methods
depending on the effects of heat introduced into the objects
is distinctly distinct from those which lie at the basis of photometry in its usual
signification.

(C. G. K.)

CELESTIAL, OR STELLAR, PHOTOMETRY

The earliest records that have come down to us regarding
the relative positions of the stars in the heavens have
always been accompanied with estimations of their relative
brightness. With this brightness was naturally associated
the thought of the relative magnitudes of the luminous bodies
from whence the light was assumed to proceed. Hence in the
grand catalogue of stars published by Ptolemy (c. 150 A.D.),
but which had probably been formed three hundred years
before his day by Hipparchus, the 1200 stars readily visible
at the naked eye in Alexandria were divided into six
classes according to their lustre, though instead of that term
he uses the word μετέχος or "magnitude"; the brightest he
designates as being of the first magnitude, and so downwards
till he comes to the minimum visible, to which he assigns
the sixth. These magnitudes he still further divides each into three.
To those stars which, though not ranged in any particular order
of brightness, nevertheless exceed the average of that order
in lustre he attaches the letter μ, the initial letter μετεχομεν (greater),
and to those in the same order which exhibit a lustre inferior to
that of the average he affixes the letter ε, the initial letter of ευσημερος.
With this sort of subdivision he passes through all the
six orders of magnitude. He does not, indeed, tell us the precise process by which these divisions were estimated, but the
principle involved is obvious. It is one of the many remarkable
instances of the acuteness and precision of the Greek mind that
for upwards of 1500 years no real improvement was made in these
estimations of lustre. J. Flamsteed estimated the estimation
of magnitude of stars visible only by the telescope, and he
improved Ptolemy's notation by writing 4.3 instead of δ, μ—
indicating thereby an order of magnitude brighter than the
average of a fourth, but inferior to that of a third—and 3.4 for
δ, ε, and so on; but it was not till the year 1766 that any real
advance was made in stellar photometry. Sir W. Herschel,
instead of assigning a particular magnitude to stars, arranged
them in small groups of three or four or five, indicating the order
in which they differed from each other in lustre at the time of
observation. This method was admirably adapted to the
discovery of any variations in brightness which might occur in the
lapse of time among the members of the group. Sir William
observed in this way some 1400 stars, published in four cata-
louges in the Philosophical Transactions from 1766 to 1799; and
two additional catalogues were discovered among his papers
in 1883 by Professor E. C. Pickering of Harvard (see Harvard
Annals, xiv. 345), and have recently been published by Colonel
J. Herschel (Phil. Trans., 1906). These researches of the
elder Herschel were in due time followed by those of his son,
Sir John, about the year 1836 at the Cape of Good Hope. He
both extended and improved the methods adopted by his father
at Slough, and by a method of estimated sequences of magnitude
he was able to arrange all the stars visible to the naked eye at
the Cape in order of the size of their relative lustre, and then to reduce his results into the equivalent magnitudes
adopted by the universal consent of astronomers. Sir John,
however, like his father, left this important labour incomplete.
Not only is the work one of great and continuous effort, but the
effects of ever-varying meteorological conditions greatly impede
it. Moreover, there is an unsatisfactory indefiniteness attending
all estimations made by the unaided eye; numerical or quantita-
tive comparisons are out of the question, and hence we find

Sir John, in the very midst of establishing his "sequences,"
adopting also an instrumental method which might lead him
to more definite results. It became clear that Sir John Herschel
concluded his photometric work at the Cape (1838) Dr F. W. A. Argelander commenced, and in 1843 completed, his Uranometria nova,
in which the magnitudes of all stars visible to the unaided eye in
central Europe are catalogued with a precision and completeness
previously unknown. It contains 3256 stars, and although
it will probably be superseded by instrumental photometry it
must ever remain a monument of intelligent patience.
Argelander's labours were not confined to stars visible to the naked
eye; by the aid of his assistants, Dr E. Schonfeld and Dr A.
Kruger, three catalogues of magnitudes and celestial co-ordinates
were subsequently published (1859-1862) as the Bonn Durch-
muertung, including the enormous number of 342,188 stars, and an additional volume containing 133,659 stars south of the
equator was published in 1886.

Dr B. A. Gould (1824-1860), in his Uranometria argentina
(1879), has done similar work for 7756 stars visible only in the
southern hemisphere, and his successor at Cordoba, J. M. Thome,
has published (1904) three volumes of the Argentine (Cordoba)
Durchmuertung containing 480,662 stars between declination
-22° to -5°. There have been other worthy labourers in the
same field, each of whom has rendered efficient service, such as
Dr E. Heis and M. J. C. Houzeau.

It is to Sir John Herschel that we are indebted for the first
successful attempt at stellar photometry by what may be termed "artificial" means. He deflected the light of the moon
(by means of the internal reflection of a rectangular prism) through a single lens 0.12 in. in diameter and of very short
focus (0.23 in.) so as to form a small artificial star in its
focus. With strings and a wooden pole he could move this
artificial star of comparison so as to be in the same line of sight with any actual star whose light he proposed to measure. Other
strings enabled him to remove it to such a distance from the eye
that its light was adjudged to be sensibly the same as that of
the star compared; and the distance was measured by a gradu-
ated tape. While he was thus busy at the Cape of Good Hope,
K. A. Steinheil at Munich had completed for Dr P. L. Seidel
an instrument nearly the same in principle but more manageable
in form. He divided the small object-glass of a telescope into
two halfs, one of which was movable in the direction of its
axis. The images of two stars whose light he desired to compare
were formed by prismatic reflection, nearly in the same line of
sight, and one of the lenses was then moved until the light of
the two images seemed equal. The distance through which it
was necessary to bring the movable lens furnished the data for
comparing the relative lustre of the two stars in question.

More recently other photometers have been devised, and de-
scriptions of three of them, with which considerable researches
have been conducted will now be given. With the first mentioned
below Professor Pickering of Harvard has made more than a
million measures with his own eyes. The results of his observa-
tions, and of those of his assistants, will be found in the Harvard
Annals especially in vol. xiv. published in 1901, which con-
tains a general catalogue of about 24,000 stars brighter than
magnitude 7.5, north of declination -40°. With the Zillner
photometer Drs Gustav Muller and P. Kempf of Potsdam have
recently completed a similar piece of work, their catalogue of
stars north of the equator brighter than 7.5 containing 14,199
stars (Potsdam Publications, 1907, vol. xvii.). The catalogue
of Professor C. Pritchard was smaller, containing 2784 stars
brighter than magnitude 6, north of declination 10°; but it was published in 1886, when very little had been done towards the
systematic measurement of the brightness of the stars (Uranometria nova oxoniensis, vol. ii. of the Oxford University
Observatory publications).

vol. xiv. and xviii.) consists of two telescopes placed side by side pointing due east, the light from the stars on the meridian being reflected into them by two mirrors inclined at an angle of 45° to this direction.

If there were a star exactly at the Pole, one of these mirrors
In 1885 systematic catalogues of stellar brightness have been constructed with all these instruments, and it has been of great interest to compare the results. The comparison has in general shown a satisfactory agreement, but there are small differences which are almost certainly systematic, due to the difference of method and instrument. One cause of such differences, the reality of which is not doubted, but the effects of which have not yet been properly fully worked out, is the "Purkinje phenomenon" (Pflügers Archiv, lxx. 297).

If a blue source of light and a red source appear equally bright to the eye, and if the intensity of each be diminished in the same ratio, they will no longer appear equally bright, the blue now appearing the brighter.

In several cases, the equalizing of two differently colored lights by the eye depends upon their intensity. It is clear that this phenomenon must affect all photometric work unless the stars are all exactly of the same colour, which we know they are not. The photographic plate of the meridian photometer and the artificial star of the Zollner photometer were equalized with a bright star A, and that they could be also compared inter se and found equally bright.

Then if a faint star B comes under observation and the intensities of the comparison stars are both reduced to equality with B, they will no longer appear equal to one another unless they are exactly the same in colour. In other words, the observed ratio of intensities of A and B will vary with the colour of the comparison star, and similarly it will also vary with the aperture of the telescope employed. Now it is one of the merits of the Potsdam catalogue above, mentioned, that it gives estimates of the colours of the stars as well as of their magnitudes—so that we now for the first time have this systematic information. In a most interesting section of their introduction it is shown that two of the Harvard photometric catalogues show systematic differences, due to colour, and amounting to nearly half a magnitude: and that the Purkinje phenomenon is a satisfactory explanation of these differences.

This is the first instance in which the effect of this phenomenon has been measured in the case of the stars, though it was known to be sensible. But there is a set of numerical results obtained in the laboratory which is of importance for all such works, viz. those obtained by Sir W. Abney (Phil. Trans. Roy. Soc. 1834) and by Dr. Zollner (1858 and 1865), giving the limiting intensity at which each pure colour vanishes. If we start with lights C D E F G of the colours usually denoted by these letters in the spectrum, and each so bright that it appears to the eye as bright as an amyl-acetate lamp at 1 ft., and if then the intensity of each be gradually diminished, the C light will disappear when the original intensity has been reduced to 22,000 ten-millionths of the original value. The other colours will disappear at the following intensities, all expressed in ten-millionths of the original: D at 350, E at 35, F at 17, and G at 15. If then we had a mixture of two lights, one of C colour as bright as before, and the other of G colour reduced in intensity (a fainter G with the other nearly bright enough to distinguish the G light at all), and if we continually reduced the combined intensity, the luminosity of the C light would diminish so much more rapidly than that of the G that the latter would begin to assert itself, and when the combined intensities were reduced to 22,000 ten-millionths of the original value, the C light would have all disappeared, while the G light would not.

Hence the colour of the light would appear pure violet, though it was originally deep red. This extreme case shows that the "last ray to disappear" when a light is gradually extinguished, may be very different in colour from that of the original light, and when more usual light-mixtures are considered, such as those of sunlight and starlight, which, though equally satisfying to the eye, "last to disappear" is found to be in the green, very near E in the spectrum. This result has two important bearings on the use of the wedge photometer. In the first place,

Dr Spitta found that internal reflections within the Nicol prism interfered with the accuracy of the result, but that this error could be eliminated by using a suitable diaphragm (Mon. Not. R.A.S. March 1890; Abney, ibid., June 1890).

Since 1885 systematic catalogues of stellar brightness have been constructed with all these instruments, and it has been of great interest to compare the results. The comparison has in general shown a satisfactory agreement, but there are small differences which are almost certainly systematic, due to the difference of method and instrument. One cause of such differences, the reality of which is not doubted, but the effects of which have not yet been properly fully worked out, is the "Purkinje phenomenon" (Pflügers Archiv, lxx. 297).

If a blue source of light and a red source appear equally bright to the eye, and if the intensity of each be diminished in the same ratio, they will no longer appear equally bright, the blue now appearing the brighter. In more general terms, the equalizing of two differently colored lights by the eye depends upon their intensity. It is clear that this phenomenon must affect all photometric work unless the stars are all exactly of the same colour, which we know they are not.

The photographic plate of the meridian photometer and the artificial star of the Zollner photometer were equalized with a bright star A, and that they could be also compared inter se and found equally bright. Then if a faint star B comes under observation and the intensities of the comparison stars are both reduced to equality with B, they will no longer appear equal to one another unless they are exactly the same in colour. In other words, the observed ratio of intensities of A and B will vary with the colour of the comparison star, and similarly it will also vary with the aperture of the telescope employed. Now it is one of the merits of the Potsdam catalogue above, mentioned, that it gives estimates of the colours of the stars as well as of their magnitudes—so that we now for the first time have this systematic information. In a most interesting section of their introduction it is shown that two of the Harvard photometric catalogues show systematic differences, due to colour, and amounting to nearly half a magnitude: and that the Purkinje phenomenon is a satisfactory explanation of these differences.

This is the first instance in which the effect of this phenomenon has been measured in the case of the stars, though it was known to be sensible. But there is a set of numerical results obtained in the laboratory which is of importance for all such works, viz. those obtained by Sir W. Abney (Phil. Trans. Roy. Soc. 1834) and by Dr. Zollner (1858 and 1865), giving the limiting intensity at which each pure colour vanishes. If we start with lights C D E F G of the colours usually denoted by these letters in the spectrum, and each so bright that it appears to the eye as bright as an amyl-acetate lamp at 1 ft., and if then the intensity of each be gradually diminished, the C light will disappear when the original intensity has been reduced to 22,000 ten-millionths of the original value. The other colours will disappear at the following intensities, all expressed in ten-millionths of the original: D at 350, E at 35, F at 17, and G at 15. If then we had a mixture of two lights, one of C colour as bright as before, and the other of G colour reduced in intensity (a fainter G with the other nearly bright enough to distinguish the G light at all), and if we continually reduced the combined intensity, the luminosity of the C light would diminish so much more rapidly than that of the G that the latter would begin to assert itself, and when the combined intensities were reduced to 22,000 ten-millionths of the original value, the C light would have all disappeared, while the G light would not.

Hence the colour of the light would appear pure violet, though it was originally deep red. This extreme case shows that the "last ray to disappear" when a light is gradually extinguished, may be very different in colour from that of the original light, and when more usual light-mixtures are considered, such as those of sunlight and starlight, which, though equally satisfying to the eye, "last to disappear" is found to be in the green, very near E in the spectrum. This result has two important bearings on the use of the wedge photometer. In the first place,
either the wedge itself should be of a greenish hue, or green light should be used in finding the scale-value (the constant B in the formula \( m = A + Bv \)). In the second, star magnitudes obtained by extinction with the wedge will agree better with those obtained by photography than those obtained with other visual photometers, since photographic action is chiefly produced by rays from E to G in the spectrum, and the E light of ultimacy in intensity with the wedge photometer is nearer this light in character than the D light with which other photometers are chiefly connected. It would also appear that results obtained with the wedge photometer are independent of the aperture of telescope employed, which is not the case with other photometers.

Passing now to the consideration of photographic methods, it is found that when a plate is exposed to the stars, the images of the brighter stars are larger and blacker than those of the fainter ones, and as the exposure is prolonged the increase in size and blackness continues. Much of the light is brought to an accurate focus, but, owing to the impossibility of perfect achromatism in the case of refractors, and to uncorrected aberration, diffraction, and possibly a slight diffusion in both refractors and reflectors, there are rays which do not come to accurate focus, grouped in rings of intensity gradually diminishing outwards from the focus. As the brightness of the star increases, or as the time of exposure is prolonged, outer and fainter rings make their impression on the plate, while the impression on the inner rings becomes deeper. Hence the increase in both diameter and blackness of the star disks. As these increase concurrently, we can estimate the magnitude of the star by noting either the increase in diameter or in blackness, or in both. There is consequently a variety in the methods proposed for determining star magnitudes by photography. But before considering these different methods, there is one point affecting them all which is of fundamental importance. In photography a new variable comes in which does not affect eye-observations, viz., the time of exposure, and it is necessary to consider how to make due allowance for it. There is a simple law which is true in the case of bright lights and rapid plates, that by doubling the exposure the same photographic effect is produced as by increasing the intensity of a source of light twofold, and so far as this law holds it gives us a simple method of comparing magnitudes. Unfortunately this law breaks down for faint lights, and Prof. W. Abney has been a vigorous advocate for the complete accuracy of this law up till 1893, in that year read a paper to the Royal Society on the failure of the law, finding that it fails when exposures to an amyl-acetate lamp at 1 ft. are reduced to \( \sigma \text{-}001 \) and "signally fails" for feeble intensities of light; indeed, it seems possible that there is a limiting intensity beyond which no length of exposure would produce any sensible effect. This was bad news for astronomers who have to deal with faint lights, for a simple law of this kind would have been of great value in the complex department of photometry. But it seems possible that a certain modification or equivalent of the law may be used in practice. Prof. H. H. Turner found that for plates taken at Greenwich, when the time of exposure is prolonged in the ratio of five star magnitudes the photographic gain is four magnitudes (Mon. Not. R.A.S. lxv. 775), and a closely similar result has been obtained by Dr Schwarzschild using the method presently to be mentioned.

Stars of different magnitudes impress on the plate images differing both in size and blackness. To determine the magnitude of the star the character of the image, the easiest Test of Magnitude, is the quantity to measure is the diameter of the image. The best method when measurements of position are being made with a micrometer, it is a simple matter to record the diameter as well, in spite of the indefiniteness of the border. Accordingly we find that various laws have been proposed for representing the magnitude of a star by the diameter of its image, though these have usually been expressed, as a preliminary, as relations between the diameter and time of exposure. Thus G. P. Bond found the diameter to increase as the square of the exposure, Turner as the cube, Pritchard as the fourth power, while W. H. M. Christie has found the law that the diameter varies as the square of the logarithm of the exposure within certain limits. There is clearly no universal law—it varies with the instrument and the plate—but for a given instrument and plate an empirical law may be derived. The photograph of a star, after all, a series of images may be produced of stars of known brightness and known exposures, and, using this as a scale of reference, the magnitudes of other images may be inferred by interpolation. A most important piece of systematic work has been carried out, by the measurement of diameters in the Cape Photographic Durchmusterung (Ann. Cape Obscr. vols. iii., iv. and v.) of stars to the tenth magnitude in the southern hemisphere. The measurements were made by Prof. J. C. Kapteyn of Groningen, on photographs taken at the Cape of Good Hope Observatory; he adopts as his purely empirical formula

\[ m = B(diameter + C) \]

where \( B \) and \( C \) are obtained independently for every plate, from comparison with visual magnitudes. \( C \) varies from 10 to 28, and \( B \) from 90 to 260. The part of the sky photographed was found to have an important bearing on the value of these constants, and it was in the course of this work that Kapteyn found a systematic difference between stars near the Milky Way and those far from it, which may be briefly expressed in the law, the stars of the Milky Way are in general bluer than the stars in other regions of the sky. It is intended, however, in the present article to discuss methods rather than results, and we cannot here further notice this most interesting discovery.

Of methods which choose the blackness of the image rather than the diameter for measurement, the most interesting is that initiated independently by Pickering at Harvard and C. Schwarzschild at Vienna, which consists in taking star images out of focus. The result is that these images no longer vary appreciably in size, but only in blackness or density; and that this gradation of density is recognizable through a wide range of magnitudes. On a plate taken in good focus in the ordinary way there is a gradation of the same kind for the faintest stars; the smallest images are all of approximately the same size, but vary in tone from grey to black. But once the image becomes black it increases in size, and the change in density is not easy to follow. The images-out-of-focus method seems very promising, to be confirmed by the published results of Dr Schwarzschild, who used a prepared comparison scale of densities, and interpolated for any given star from it. The most satisfactory photographic method would certainly be to take account of both size and blackness, i.e. to measure the total deposit in the film; as, for instance, by interposing the whole image in a given beam of light, and measuring the diminution of the beam caused by the obstruction. But no considerable piece of work has as yet been attempted on these lines.

Even in a rapid sketch of so extensive a subject some notice must be taken of the application of photometry to the determination of the relative amount of light received on the earth from the sun, the moon and the planets. The methods by which these ratios have been obtained are as simple as they are ingenious; and for them we are mainly indebted to the labours of P. Bouguer and W. C. Bond (1789-1859). The former compared the light received from the sun with that from the moon in the following fashion in 1775. A hole one-twelfth of a Paris inch was made in the shutter of a darkened room; close to it was placed a concave lens, and in this way an image of the sun 9 in. in diameter was received on a screen. Bouguer found that this light was equal to that of a candle viewed at 16 in. from his eye. A similar experiment was repeated with the light of the full moon. The image now formed was only two-thirds of an inch in diameter, and he found that the light of this image was comparable with that of the same candle viewed at a distance of 50 ft. From these data and a very simple calculation it followed that the light of the sun was about 256,289 times that of the moon.
of the sun. Other experiments followed, and the average of all the results was that the light of the sun was about 300,000 times the average light of a full moon, both being viewed in the heavens at the same altitudes. The details will be found in Bouguer’s Traité d’optique. W. H. Wollaston in 1829 tried a series of experiments in which 3972 was obtained; but the omission of certain necessary precautions vitiates the result (Phil. Trans. 1839). Bond (Mem. Amer. Acad. 1861, p. 295) adopted a different process. He formed the image of the sun on a silvered globe of some 10 in. diameter; the light of this image was reflected on to a small mercurial thermometer bulb; and then this second image was compared with a Bengal light so moved that the lights appeared to be equal. The same process was adopted with the full moon instead of with the sun. The result was that the sun’s light was 470,960 times that of the moon. Seidel long before this date had compared the light of the mean full moon with that of Jupiter in mean opposition; his result is 6430. So also this light of Jupiter was found to be 4864 times that of Venus at her brightest; and Jupiter was found to give 8.2 times the light of a Lyrae. If, then, these numbers could be accepted with confidence, we should have the means of comparing the light received from the sun with that received from any of the stars. Adopting these precarious numbers on the authorities of Bond and Seidel we have the following results:—

| Sun’s light | 470,960 |
| Venus at her brightest | 622,000 |
| Jupiter at mean opposition | 5970 |
| Sirius | 2000 |

Lastly, Bouguer, by comparing the light of the full moon viewed at different altitudes with a artificial light, found that the atmosphere absorbs 1877 of the light incident on it at the zenith of any place. Professor Pritchard, from photometric measures taken at Cairo, found this number to be 157. At Oxford it was 209. Thus Bouguer’s determination indicates an absorptive capacity in the atmosphere of Britain just midway between those of Oxford and Cairo. Seidel at Munich expresses “surprise” at finding his own results so nearly accordant with Bouguer’s. Although rather outside the domain of photometry in the strict sense, a word or two may be said here about recent attempts to measure the heat received from the stars, the first being made with the “radio-micrometer” of C. V. Boys. (Proc. Roy. Soc. 1890). This is an extremely delicate instrument for measuring radiant heat, and consists of a very light thermo-electric circuit (two tiny bars of antimony and bismuth soldered together at one edge, the outer edges being connected by a hoop of copper wire) suspended by a quartz fibre (a torsion fibre of the very greatest sensitiveness) in a strong magnetic field. A minute quantity of radiant heat falling on one of the junctions of the circuit sets a current in the circuit, which thus rotates in the magnetic field until brought to rest by the torsion of the fibre. For use on the heavenly bodies the radiant heat is collected to focus by a reflecting telescope (an object-glass would absorb it), and when the telescope is pointed to the moon the varying radiation from different parts of the disk is beautifully shown. No heat comes from the unlit portion, and of the illuminated portion the maximum is obtained from near the limb. But when pointed to the brightest stars no indications were obtained, although the instrument is sensitive enough to detect the heat from a candle more than a mile off. It seems certain that indications of heat from the stars obtained by previous observers must be spurious. It is also manifest that to obtain satisfactory results even more sensitive apparatus must be devised, and by using a radiometer and the powerful resources of the Verres Observatory E. F. Nichols succeeded in 1868 and 1869 in obtaining indications of heat from Arcturus and Vega, as well as from Jupiter and Saturn (Astrophysical Journ. xiii., 191), the heat received being comparable with that from a candle 6 m. away. We may place alongside this result that obtained by W. J. Dibdin (Proc. Roy. Soc. April 1893), who compared candle-light with twenty-one stars ranging to the sixth magnitude, and found the light of a second magnitude star equal to that of a candle at 1200 ft.

PHRAATES (PHRAATES; PERS. Frahat, modern Forhät), the name of five Parthian kings.

1. PHRAATES I., son of Priapatus, reigned c. 175–170 B.C. He subdued the Mardi, a mountaneous tribe in the Elburz (Justin xiii. 7); said (Charac. 7). He died young, and appointed as his successor not one of his sons, but his brother Mithradates I. (Justin xii. 9).

2. PHRAATES II, son of Mithradates I., the conqueror of Babylonia, reigned 138–127. He was attacked in 139 by Antiochus VII. Sidetes, who, however, in 129 was defeated and killed in a great battle at Media, which ended the Seleucid rule east of the Euphrates (see Seleucid Dynasty). Meanwhile the kingdom was invaded by the Sicythians (the Tochari of Bactria), who had helped Antiochus. Phraates marched against them, but was defeated and killed (Justin xiii. 1; Johannes Antioch. fr. 60).

3. PHRAATES III., “the God” (Phlegon, fr. 12 ap. Photius cod. 97 and on some of his coins), succeeded his father, Sanatruces, in 70 B.C., at the time when Lucullus was preparing to attack Tigranes of Armenia, who was supreme in western Asia and had wrested Mesopotamia and several vassal states from the Parthian kingdom. Naturally, Phraates declined to assist Mithradates of Pontus and Tigranes against the Romans (see Tigranes). He supported his son-in-law, the younger Tigranes, when he rebelled against his father, and invaded Armenia (65 B.C.) in alliance with Pompey, who abandoned Mesopotamia to the Parthians (Dio. Cass. xxxvi. 45; 57; Appian, Mithr. 104; Liv. Epit. 100). But Pompey soon overrode the treaty; he acknowledged the elder Tigranes, took his son prisoner, occupied the vassal states Gordyene and Oroene for the Romans, and denied the title of “king of kings,” which Phraates had adopted again, to the Parthian king (Plut. Pompe. 33; 38; Dio. Cass. xxvii. 5 seq.). About 57 Phraates was murdered by his two sons, Orodes I. and Mithradates III.

4. PHRAATES IV., son of Orodes I., by whom he was appointed successor in 37 B.C., after the death of Pacorus. He soon murdered his father and all his thirty brothers (Justin xii. 3; Plut. Cross. 35; Dio Cass. xlix. 23). He was attacked in 36 by Antonius (Mark Antony), who marched through Armenia into Media Atropatene, and was defeated and lost the greater part of his army. Believing himself betrayed by Artavasdes, king of Armenia, he invaded his kingdom in 34, took him prisoner, and concluded a treaty with another Artavasdes, king of Atropatene. But when the war with Octavianus Augustus broke out, he could not maintain his conquests; Phraates recovered Atropatene and drove Artaxes, the son of Artavasdes, back into Armenia (Dio. Cass. xlix. 24 seqq.; 39 seqg.; cf. li. 16; Plut. Antonius, 37 seqq.). But by his many cruelties Phraates had roused the indignation of his subjects, who raised Tiridates II. to the throne in 32. Phraates was restored by the Sicythians, and Tiridates fled into Syria. The Romans hoped that Augustus would avenge the defeat of Crassus on the Parthians, but he contented himself with a treaty, by which Phraates gave back the prisoners and the conquered eagles (20 B.C., Mon. Anc. 5, 40 sqq.; Justin xiii. 5); the kingdom of Armenia also was recognized as a Roman dependency. Soon afterwards Phraates, whose greatest enemies were his own family, sent five of his sons as hostages to Augustus, thus acknowledging his dependence on Rome. This plan he adopted on the advice of an Italian concubine whom he made his legitimate wife under the name of “the goddess Musa”; her son Phraates, commonly called Phraatases (a diminutive form), he appointed successor. About 4 B.C. he was murdered by Musa and her son (Joseph. Anti. xvi. 2, 4).

5. PHRAATES V., or PHRAATASES, the younger son of Phraates IV. and the “goddess Musa,” with whom he is associated on his coins. Under him a war threatened to break out with Rome about the supremacy in Armenia and Media. But when Augustus sent his adopted son Gaius Caesar into the east in order to invade Parthia, the Parthians preferred to conclude a
treaty (A.D. 1), by which once again Armenia was recognized as
in the Roman sphere (Dio. Cass. iv. 10; Velleius ii. 101). Soon
after Phraataces and his mother were slain by the Parthians,
about A.D. 5 (Joseph. Ant. xvii. 2, 4).
(PHRAATZ, GEORGE [GEORGES PHRANTEZ] (1401-c. 1477)
the last Byzantine historian, was born in Constantinople. At
an early age he became secretary to Manuel II. Palaeologus.
He was governor of Sparta, and subsequently great logothete
(chancellor). At the capture of Constantinople by the Turks (1453)
he fell into their hands, but managed to escape to Peloponnesus, where
he obtained protection at the court of Thomas Palaeologus, despot
of Achaen. After the downfall of the Peloponnesian princes
(1460) Phraortes retired to the monastery of Tarchaniotes in
Corfu. Here he wrote his Chronicle, containing the history
of the house of the Palaeologi from 1258-1476. It is a
most valuable authority for the events of his own times.

Editions by I. Bekker (1838) in the Corpus scriptorum hist. by
and in P. Migne, Patrologia graeca, c1vii; see also C. Krumbacher, Geschichter der byzantinischen Litteratur (1897).

PHRAORTEST, the Greek form of Fravoritz, king of Media.
According to Herodotus (i. 102) he was the son of Deioches, and
began the Median conquests. He first subjugated the Persians,
and then a great many other peoples of Asia, till at last he
attacked the Assyrians, but was defeated and killed in a battle,
after a reign of twenty-two years (about 646-625 B.C.; but
perhaps, as G. Rawlinson supposes, the fifty-three years of
Deioches ought in reality to be transferred to him). From other
sources we obtain no information whatever about Phraordest,
but the data of the Assyrian inscriptions prove that Assurb-anu-
pal (see BABYLONIA and ASSYRIA), at least during the greater
part of his reign, maintained the Assyrian supremacy in Western
Asia, and that in 645 he conquered Susa. The Medianos too
were subject to him as far as the Elburz and the central Iranian
desert.

When after the assassination of Smerdis all the Iranian tribes,
the Babylonians and the Armenians rebelled against Darius
and the Persian rule, "a man of the name of Fravartish (i.e.
Phraores), a Mede, rebelled in Media and spoke to the people thus:
I am Khshathrita, of the family of Uvakhshata (Cyzaxares)." He
reigned for a short time, but was defeated by Cyrus, and afterwards by Darius himself, taken prisoner in
Rhage (Rai), and executed in Ebcaza (530 B.C.; see
inscription of Darius at Behistun).

(PHRAZES) PHRENOLOGY, from Gr. φρήν, mind, and λόγος, discourse,
the name given by Thomas Ignatius Forster to the empirical
system of psychology formulated by F. J. Gall, and developed
by his followers, especially by J. K. Spurzheim and G. Combe,
by whom it was named "craniocopy," "craniology," "physiognomy" or "zoonomy." The principles upon which
it is based are five: (1) the brain is the organ of the mind;
(2) the mental powers of man can be analysed into a definite
number of independent faculties; (3) these faculties are innate,
and each has its seat in a definite region of the surface of the
brain; (4) the size of each such region is the measure of the
degree to which the faculty seated in it forms a constituent
element in the character of the individual; (5) the correspond-
ence between the outer surface of the skull and the contour
of the brain-surface beneath is sufficiently close to enable the
observer to recognize the relative sizes of these several organs
by the examination of the outer surface of the head. It
professes primarily to be a system of psychology, but its second
and more popular claim is that it affords a method whereby the
disposition and character of the subject may be ascertained.

Phrenology is not a system of psychology, but certain
views connected with the action of the brain has been recognized from
a very early age of philosophy. It is true that Aristotle
describes the brain as the coldest and most bloodless of bodily
organs, of the nature of water and earth, whose chief purpose is
to temper the excessive heat of the heart, as the cooler regions
of the firmament condense the vapours rising from the earth.

In his view, as in that of most of the earlier writers of such
nations of antiquity, the heart is the seat of life; to it, not to the
brain, the Hebrew writers refer thoughts and affections, while
they considered judgment as seated sometimes in the head,
sometimes in the kidneys. This was likewise the teaching of
the Egyptian philosophers; and hence, while many rites
were practised and prayers offered for the preservation of
the heart of the deceased, there were none for the conservation of
the brain. We learn from Diogenes Laertius that Pythagoras
held more accurate physiological views, as he taught that the
mind and the intellect have their seat in the brain. The theory
of Hippocrates was Pythagorean rather than Aristotelian, for,
although in one passage in his work De corde he expresses himself
doubtfully, yet elsewhere he clearly states that he considers
the brain to be the index and messenger of the intellect. The
cerebral seat of sense-perception is also taught by Plato,
who puts into the mouth of Socrates the theory that the brain is the
organ affected by the senses, whereby memory and opinion arise,
and from whence knowledge springs. The classic poets also
notice this dependence of mind on brain; for example, in the
Clouds (v. 1726) Strepsiades accuses Amyntas of not being in
his right mind, and, on being asked why, responds, "You seem
to me as if you had had a concussion of the brain."

The two founders of anatomical science, Erasistratus and
Herophilus, who lived in the days of Ptolemy Soter, taught not
only that the brain was the seat of sensation and of intellect,
but also that there was therein a certain degree of localization
of function. Erasistratus believed that the sensory nerves arose
from the brain, which was the seat of the moral and mental
operations. Herophilus was apparently the first who held that
the vital forces resided in and circulated from the ventricles of
the brain, at least so we gather from Celcus and the other authors
who have preserved his views. By the influence of the writings
of Galen, which directly teach that the brain is the seat of soul
and intellect the Pythagorean doctrine prevailed among the later
philosophers. According to the Galenic theory the animal
spirits have their origin in the ventricles of the brain, and pass
into the heart from which they are conveyed by the arteries
through the body. Galen in one place (viii. 139) refers their
origin to the brain-substance, but the ventricular theory was that
adopted by his followers, some of whom suggested that there was
some relation between the shape of the head and the character
and disposition of the mind. The Arabian physicians Averroes
and Rhazes adopted the Galenic doctrine and developed the
hypothesis of a fourfold ventricular localization of faculties,
which the Greeks had originated. Avicenna added to these a
fifth region. Such of the early Christian authors as referred in

1 In the Chaldee portion of Daniel (ii. 28, iv. 5, vii. 1) visions and
thoughts are referred to the head. For other particulars as to early
views see Nasse on the psychical relations of the heart in Zeitschr. j.
psychische Erze (1818), vol. i. A few of the later medical writers
express similar views; see Santa Cruz Ursinus media, Madrid (1624).

2 Book of the Dead, ch. xxvi.-xxx.
3 viii. 30; ed. Cobet, Paris (1850), p. 211, horæ dii, no. in G 4
4 De morbo sacro, op. ed. Kühn, i. 612 seq.; also Epist. iii.
824. Among later writers Licetus of Genoa taught the co-extension
of soul and body, upon which subject he wrote two books (Padua,
1616). In this connexion may be noted a curious work by Schegius,
De anima in corpore, which expresses the idea that the seat of
the passions is in the great head.

5 Quoted, it is true, in the Comment. in Arist., Latin tr. (Venice, 1563), vii. 73.
6 De imaginio in dibus in verbo circulis anterioribus perfectum cogitatio vero in medio expellet. Moria autem posteriorum possidet ventriculum. De re medica, Gerard's trans. (Basel, 1554), i. 9.
7 Lib. canonis (1507), p. 19, and De naturalibus, c. 6.
PHRENOLOGY

535

their writings to the relation of soul to body naturally adopted the teaching of Galen which they accommodated to their theology, thereby conferring on it an importance which rendered correction difficult. Tertullian in a sense expresses his belief in a theory of localization as also at a later period does Thomas Aquinas.

Early in the 13th century Albertus Magnus gave a detailed description of the distribution of mental and psychical faculties in the head. The anterior region he assigned to judgment, the middle to imagination, and the posterior to memory. A somewhat similar allocation was made by Gordon, professor of medicine in Montpellier (1290), who assigned common sensation and the reception of impressions to the anterior cornua of the lateral ventricles, phantasia to the posterior, this being two-fold (imaginativa and cogitativa), judgment or astitmetia to the third ventricle, and memory to the fourth. Figures of a similar division were given by Petrus Montagnana and Lodovico Dolce still later by Ghirardelli of Bologna and by Theodore Gall of Antwerp. That the "vital spirits" resided in the ventricles was doubted by many, and denied by a few of the anatomists of the 17th century.

G. Baulin in 1621 attacked the old view, and Hoffmann of Altorf showed that, as the ventricles were closed cavities, they could not transmit any material fluid. That these spirits existed at all was doubted by Alexander Benedictus, Plater, and a few others; but they were believed in by the great majority of 17th and even of 18th century medical writers, many of whom conceived that the ventricles were semper pleni spiriribus animalibus flammae similibus, quorum beneficis intelligimus, sensitum, et moverum, and the choroid plexus was strongly assailed by J. Kislak and others as to revolutionary. Columbus ridiculed the idea that the convoluted surface can have anything to do with intellect, as the ass, a proverbially stupid animal, has a convoluted cerebrum. According to his view, the convolutions are for the purpose of lightening the brain and facilitating its movements. The grey matter of the surface of the cerebrum was recognized as the true dynamic element by M. Malpighi and T. Willis.

2 Summa theologiae, ed. Migne, i. 1094, 1106-7. Prochaska and his translator, Laycock (Mind and Brain, ii. 163), charge Duns Scotus with holding this view; probably he did, but he does not express it, as he simply specifies the cerebrum and its root, the spinal cord, as the source of the nerves along which sensory impulses travel. Comment. de anima, i. 515 (Leiden, 1637).

3 Opera, iii. 124, vi. 1651.

4 Litium medicinae, 101 (Venice, 1694).

5 Avicenna's fifth region is interposed between imaginativa and astitmetia (De naturallus, c. vi.). Thomas Aquinas combines the lambda of Archimedes with the choroid plexus. He says, on the other hand, he says of ratio particularis, "medici assignant determinatum organum, scleret medium partem capitit" (i. 1106).

The latter regarded the convoluted surface of the cerebrum as the seat of the memory and the will, the convolutions being intended to retain the animal spirits for the various acts of imagination and memory. Imagination he described as seated in the corpus callosum, sense-perception in the corpus striatum, and impetus et perturbation in the basal parts of the cerebrum above them. The cerebellum he regarded as the centres of sight and the cerebrellum of involuntary acts. Succeeding anatomists simply varied these localizations according to their respective fancies. G. M. Lancisi placed sense-perception in the corpus callosum, R. Vivescens in the centrum ovale majus. R. Descartes supposed the soul to be seated in the pineal gland, others in the brain-commissures especially the pons Varoli. Meyer considered abstract ideas to arise in the cerebellum, and memory to have its seat at the roots of the nerves.

Of later writers three deserve special notice, as having largely prepared the way for the more modern school of phrenology. J. A. Unzer, of Halle, in his work on physiology extended the pre-existing theories of localization. Metzger, twenty years before the publication of Prochaska's work, had proposed to make a series of observations on the anatomical characters of the brains of persons of marked intellectual peculiarity; but apparently he did not carry this into effect. In a more special manner Prochaska of Vienna may be looked upon as the father of phrenology, as in his work on the nervous system, published in Vienna in 1784, are to be found the germs of the later views which were propounded in that city twelve years later.

The system formulated by Gall (q.v.) is thus a modern expansion of an old empirical philosophy, and its immediate parentage is apparent. Although, according to Gall's account, it was with him the result of independent observations, these, he tells us, he began to make at an early age, by learning to correlate the outward appearances and mental qualities of his schoolfellows. Gall's first published paper was a letter in the Deutscher Merkur of December 1798, but his principal expositions were oral, and attracted much popular attention, which increased when, in 1802, he was commanded by the Austrian government, at the instance of the ecclesiastical authorities, to discontinue his public lectures. In 1804 he obtained the co-operation of Spurzheim (1776-1832), a native of Longwich, near Treves, who became his pupil in 1800, and proved a powerful ally in propagating the system. The Master and pupil at first taught in harmony, but they soon found it advisable to separate in 1813; and we find Spurzheim, several years after their parting, declaring that Gall had not introduced any improvements into his system since their separation (notes to Chenevi, p. 99). "My philosophical views," he also says, "widely differ from those of Gall." In Paris, where he settled in 1807, Gall made many influential converts to his system. F. J. V. Broussais, H. M. D. de Blainville, H. Croquet, G. Andrall, E. Geoffrey St-Hilaire, Vimont and others adopted it and counteracted its progress. Gall visited Great Britain, but the diffusion of phrenology here was chiefly due to Spurzheim, who lectured throughout the country and through America, and with the aid of his pupil, George Combe, attracted a large popular following. His most influential disciples were J. Elliotson, Andrew Combe, Sir G. S. Mackenzie, R. Macniss, T. Laycock and Archbishop R. Whately, and in America Caldwell and J. Godman. On the opposite side many influential men took up a strongly antagonistic position, prominent among whom were J. Barclay the anatomist, F. M. Roget, Sir Charles Bell, Sir W. Hamilton, F. Jeffrey, H. P. Brougham, T. Brown and Sir B. Brodie. The nature of the system rendered it eminently fitted to catch public attention, and it rapidly attained to so great a

17 Fechner, Elemente der Psychophysik, ii. 396.

18 Some of the medieval views were very fanciful, thus Shabbethai b. Abraham, the earliest Jewish writer on medicine (d. A.D. 959), thought that the spirit of life has its seat in the brain membranes, all which were over the brain, as the back in the heavens arched over the earth and waters. See Der Mensch als Gottes Ehenbild, ed. Illienick (Leipzig, 1854), and Castelli, Commento (Florence, 1880).

19 Vemichtliche medicinische Schriften (1764), i. 58.

degree of popularity that in 1832 there were twenty-nine phrenological societies in Great Britain, and several journals devoted to phrenology in Britain and America; of these the Phrenological Journal, a quarterly, edited chiefly by George Combe with aid from others of the Edinburgh confraternity, notably Sir George Mackenzie and Macnish, "the modern Pythagorean," lived from 1823 to 1847, through twenty volumes. The controversy in many places was heated and often personal, and this largely increased the popular interest. In the Edinburgh Review the theory was severely criticized by Thomas Brown, and afterwards in a still more trenchant manner by Jeffrey. In Blackwood it, was ridiculed by Professor John Wilson. Being a subject which lent itself easily to burlesque, it was parodied cleverly in a long rhyme by two authors, "The Craniad," 87 pages long, published in 1817, while, on the other hand, verse was pressed into its service in the rhyme "Phrenology in Edinburgh" in 1824.  

The best defence of the system was that by Chenevix in the third number of the Foreign Quarterly, afterwards reprinted with notes by Spurzheim.  

The Faculties and their Localities.—The system of Gall was constructed by a method of pure empiricism, and his so-called organs were for the most part identified on slender grounds. Having selected the place of a faculty, he examined the heads of his friends and casts of persons with that peculiarity in common, and in them he sought for the distinctive feature of their characteristic trait. Some of his earlier studies were made among low associates, in gaols and in lunatic asylums, and some of the qualities located by him were such as tend to become perverted to crime. These he named after their excessive manifestations, mapping out organs of murder, theft, &c.; but as this cast some discredit on the system the names were changed by Spurzheim, who claimed as his the moral and religious considerations associated with it. Gall marked out on his model of the head the places of twenty-six organs as round enclosures with vacant interspaces. Spurzheim and Combe divided the whole scalp into oblong and conterminous patches (see the accompanying figures). Other methods of division and other names have been suggested by succeeding authors, especially by Cox, Sidney Smith (not Sydney), Toulmin Smith, K. G. Carus of Dresden, Don Mariano Cubi I Solar, W. B. Powell of Kentucky, J. R. Buchanan of Cincinnati, Hittel of New York. Some, like the brothers Fowler, raise the number of organs to forty-three; but the system of Spurzheim and Combe is that which has always been most popular in Britain. Spurzheim separated the component faculties of the human mind into two great groups and subdivided these as follows:—

I. Feelings, divided into—

1. Propensities, internal impulses inviting only to certain actions.
2. Sentiments, impulses which prompt to emotion as well as to action.
A. Lower—those common to man and the lower animals.
B. Higher—those proper to man.

II. Intellectual faculties:—
1. Perceptive faculties.
2. Reflective faculties.

In the following list the locality and the circumstances of the first recognition of the organ are appended to the names, which are mostly the inventions of Spurzheim. Gall's names are placed in brackets."

**Propensities.**

1. Amativeness (Instinct de la génération), median, below the inion; first determined by Gall from its heat in an hysterical widow, supposed to be confirmed by many observations, and referred to the cerebellum.

2. Philoprogenitiveness (Amour de la procréation), median, on the squamous sinuus, and selected as the organ for the love of children because this part of the skull is usually more prominent in apes and in women, in whom the love of children is supposed to be stronger than in men.

3. Concentrative, below the obelon and over the lambda. This is a region of uncertain function, unnoticed by Gall, but described as Inhabitativeness by Spurzheim, because he found it large in cats and in a clergyman fond of his home. It has since been considered by Combe to be the seat of the power of concentration, whereof he believed Inhabitativeness to be a special case.

4. Adhesiveness (Amity), over the lateral area of the lamboidal suture. This region was prominent in a lady introduced to Gall as a model of friendship, and is said by him to be the region where persons who are closely attached put their heads together.

5. Combativeness (Instinct de la défense), above the asterion; it was found by Gall by examining the heads of the most quarrelsome and his low companions whom he had beforehand stimulated by alcohol. It was verified by comparing this region with the same part of the head of a quarrelsome young lady.

6. Destructiveness (Instinct carnassier), above the ear meatus. This is the widest part of the skulls of carnivorous animals, and was found large in the head of a student so fond of torturing animals that he became a surgeon, also large in the head of an apothecary who became an executioner.

7. Self-esteem (Orgueil, fierté), at and immediately over the obelon; found by Gall in a traitor who excused his poverty on account of his pride. This was confirmed by the observation that proud persons held their heads backwards in the line of the organ.

8. Love of Approval (Vénération), outside the obelon; the region in which Gall saw the evidence on the head of a lunatic who fancied herself queen of France.

9. Cautiousness (Circumspection), on the parietal eminence; placed here because an ecclesiastic of hesitating disposition and a vacillating councillor of state had both large parietal eminences.
PHRENOLOGY

Superior Sentiments.
13. Benevolence (Bonté), on the middle of the frontal bone in front of the coronal suture; here Gall noticed a rising on the head of the highly commended servant of a friend, as well as on a benevolent schoolmate who nursed his brothers and sisters when they were sick. In Galvani's observations referred the intellectual powers.
14. Veneration (Sentiment religieux), median at the bregma. Gall noted when visiting churches that those who prayed with the greatest fervour were prominent in this region, and it was also prominent in a pious heart.
15. Conscientiousness, Believiness (Forster) unknown to Gall; recognized by Spurzheim usually from its deficiency, and placed between the last and the frontal eminence. Spurzheim found, in F. Rabelais and J. Swift.
16. Firmness (Fermeté), median on the sagittal suture from behind the bregma to the front of the occlusion. Lavater first pointed out that persons of determination had lofty heads.
17. Hope, Gall, who believed hope to be akin to desire and a function of every faculty which desires and left this territory unallocated.
18. Wonder, said to be large in vision-seers and many psychic researchers. A second similar organ placed between this and the next is called Mysteriæziness by Forster, and is said to be the seat of belief in ghosts and in the supernatural.
19. Idenity (Poésie), noted by Gall from its prominence in the bones of poets, said to be the part touched by the hand when composing poetry.
20. Wit (Esprit caustique), the frontal eminence, the organ of the Wit, according to Spurzheim in F. Rabelais and J. Swift.
21. Imitation (Faculté d'imiter), disposition to mimicry, placed between Benevolence and Wonder.

Perceptive Faculties.
22. Individuality, over the frontal sinuses in the middle line; the capacity of recognizing external objects and forming ideas therefrom; said to have been large in Michelangelo, and small in the Sibyls.
23. Form (Mémoire des personnes), capacity of recognizing faces; gives a wide interval between the eyes; found by Gall in a squinting girl with a good memory for faces.
24. Weight, outside the last on the orbital edge; and, like it, over the frontal sinuses. The prominence of ridge here is due to large sinuses or a projecting bone. Certain old writers, such as Strato Physicus, located the whole intellect in this ridge.
25. Colour, on the external angular process of the frontal bone, large in a calculating boy in Vienna.
26. Order, internal to the last, first noted by Spurzheim in an orderly idiot.
27. Eventuality (Mémoire des choses), the median projection above the glabella, supposed to be the seat of the memory of events.
28. Time, below the frontal eminence and a little in front of the temporal.
29. Tone (Sens des rapports des tons), on the foremost part of the temporal muscle, where Gall noticed a bulge on the head of a musical prodigy of five.
30. Language (Sens des mots), behind the eye. This was the first organ noticed by Gall, as a clever schoolfellow, quick at languages, had prominent eyes. Old authors had noted the connexion between prominent eyebrows and mental development; thus Gazzali and Syenenas Medicus Cyprius place the intellect and soul behind the eyebrows.

Reflective Faculties.
31. Comparison (Sagacité comparative), median, at the top of the bare region of the forehead, where a savant friend of Gall’s, fond of analogies, had a prominent brow.
32. Causality (Esprit métaphysique), the eminence on each side of the orbit, noticed by the head of Fichte and on a bust of Kant; the seat of the faculty of correlating causes and effects.
33. First identification of each organ was made by an induction from very limited data, but the founders and exponents of the system have collected a considerable number of each of these regions coexisted with increased powers of the faculty supposed to reside therein, and in some cases they have discovered coincidences of a surprising nature. When, however, such do not exist, a convenient excuse is found by reference to the indefinite article of temperament, or by a supposed explanation of the faculty in question as not simple but produced by the co-operation of other influences. Thus, as Sheridan’s bump of wit was small, he is said not to have been a writer; but to have had composition and memory strongly developed. The girl Labrosse (described in Fergusson’s Bulletin for October 1831), who exhibited strong amativeness but had a rudimentary cerebellum, is said to have obliterated it by over-use. Thurtell, a cold-blooded murderer, whose organ of benevolence was large, is said to have been generous, as he once gave half-a-guinea to a friend, &c.

The method whereby the sizes of organs are estimated is arbitrary and the boundaries of the regions indefinite. The attempts of Nicol, Stratton and Wight to devise mechanical and accurate modes of measurement have not been very successful and have not found favour with the professional phrenologist.

Anatomical Aspect of Phrenology.—The phrenological controversy served the useful purpose of stimulating research into the anatomy of the brain; but we owe very little of solid progress to the advocates of the system. Gall is the only writer of his creed in whose works original observations of value are to be found, and Dr B. Holländer has cited many interesting and carefully recorded anatomical and clinical facts in his writings. Although the study of the surface of the cerebrum is the essence of phrenology, yet nowhere in the circle of phrenological literature are the convolutions of the brain accurately described; our knowledge of their order and disposition comes from the morphologist, not from the phrenologist. The first real step towards their systematic description was made by L. Rolando, who in 1830 described the fissure to which his name is attached, and very little advance was made until the publication in 1856 of L. P. Gratloët’s and Huschke’s memoirs. These works for the first time placed the description of the surface of the brain, imperfectly attempted by L. A. Desmoulins in 1825, on a satisfactory basis.

A description of the anatomy of the brain is given under the heading BRAIN, so it is necessary here only to refer to points not included in that account.

1. Any psychological theory which correlates brain-action and mental phenomena requires a correspondence between brain-size and mental power; and, speaking generally, the brains of those whose capacities are above the average are larger than those of the general run of their fellow-men.

2. Direct measurements of the relative developments of different portions of brains are difficult and troublesome to make; but their importance to phrenologists is so great that it is remarkable that no attempts to obtain any such were made by them. The series given by R. Wagner of the relative sizes of the cerebral lobes of four brains is almost the only record of importance in this direction, and is appended.

From this it appears that the woman exceeded Gauss in perceptive and reflective organs, exceeded Fuchs in sentiment, and fell behind both workers in comparison. Which organs are the most advanced, and therefore have the greatest value, is the great plan is fairly uniform. A still more important question has been recently raised by J. N. Langley, viz. how far identical spots on

1. Della Struttura degli emisferi cerebral (Turin, 1830).
3. Gall, Buchs, Straton, and Wight, who thought that the phrenological divisions do not accurately coincide with the anatomical. It would furnish important physiological data if the brains of men distinguished for special qualities were examined in this or some comparable way.

3. It is in relation to phrenology to ascertain the constancy of the convolutions. Many varieties in the detail of the surface-patterns have been recorded by Tschudi, Poggi, Gall, and others, and from this it appears that the general plan is fairly uniform. A still more important question has been recently raised by J. N. Langley, viz. how far identical spots on

identical convolutions in different brains consist of nerve-cells with precisely the same connections. The observance of this arrangement results from volition of brain-surface under constraint, hence as the different tracts of surface undergo proportional overgrowth they may fold along different lines. The occurrence of small differences in the rate of this overgrowth, tested to be by the dimensions of the convolutions, can hardly fail to cause considerable alteration in the place of definite territories of grey cells. Some method for the determination of the limits of these shifting is of right to be confirmed by additional observations. Thus Rolando and his ganglion-cells of the fourth layer are of large size (giant-cells of Betz), and in the convolutions of the tempero-sphenoidal lobe larger cell angles are observed, and separated by a distance between the larger pyramidal and the ganglion-cells, so that, while in the part of the brain above the fissure of Sylvius the gray cortex is for the most part five-layered, below and behind that fissure it is six-layered. Between the temporal lobe and the part of the brain above the fissure of Rolando the ganglion-cells are of the size of giant-cells of Betz, and in the convolutions of the tempero-sphenoidal lobe larger cell angles are observed, and separated by a distance between the larger pyramidal and the ganglion-cells, so that, while in the part of the brain above the fissure of Sylvius the gray cortex is for the most part five-layered, below and behind that fissure it is six-layered.

The growth of the brain proceeds with rapidity, the growth during a large part of this period averaging one cubic centimetre daily. This enormous increase is chiefly due to the rapid development of medullated nerve-fibres, which are deficient in the foetal brain. During the second and third years growth takes place more slowly, the occipital and parietal lobes increasing more than the frontal or tempo-sphenoidal. During these and the four succeeding years the base elongates commensurately with the increase of the skull. During the first years the frontal lobes grow faster than the parietals, and at seven the average brain has attained the weight of 1340 grammes, being the weight of the body as 12:20. In the following years the rate of growth is at a slower pace, but at puberty the whole brain grows actively, especially the frontal lobes. This activity lasts until about eighteen years of age, then diminishes; but the average brain does not reach its maximum size until about one or two or three years after that period when the brain tends to diminish towards senility.5

5. The estimation of the relative development of grey and white matter in the several lobes is important not only to any theory of cerebral dyscharges, which allocates functions specifically to the separate part of the brain-surface; but no attempt has been made by the phrenologist to obtain precise results in this direction, nor even do we possess any definite results in that form.

The recently introduced method of Bourgoing and B. Danilewski, based upon the differing specific gravities of grey and white matter, promises to give definite information as to the relative amounts of these forms of brain-matter; but further experiments are needed to perfect the method.6

6. The relations, if any, between the alterations which take place in the shape and position of the head and alterations in brain-surface have not been specifically described. It has been said to have said that his organ of causality had enlarged with increasing use, and a list of cases of similar alterations of head-shape is given by Deville (Phren. Journ. xiv. 32), most of which are simply age-changes, and are described as having occurred to the centre of the head.

Trans., 1870). There are no exact measurements recorded which indicate the occurrence of topical increases of a normal brain in situ. The following is from the report made by the Journ. of the Physiological Society on the measurement of the human skull.

All the so-called cases are given vaguely, without measurements, and the careful measurements of George Combe in such cases as were available to him showed no appreciable alterations in adult heads even at long intervals of time (see also Andrew Combe, Phren. Journ. x. 414).

7. The phrenological want of knowledge of the topography of the brain-surface was necessarily correlated with ignorance of the exact relations of the convolutions to the interior of the cranial bones; these have been carefully worked out by E. Hüsche, Hefler, W. A. Turner, Cunningham and Reid. Some latitude, however, must be allowed in topography, as the exact relation of some of the convolutions of the cerebral cortex is not yet decided.

The fissure of Rolando is perceptibly farther back from the coronal suture in dolichocephalic than in brachycephalic skulls, and it is still farther back in the extreme boat-shaped form of long-headedness. 

Passet shows that there is a slight topographical difference in the two sexes (Arch. f. Anthrop., 1882, xiv. 89), and in the heads of those with a symmetrically-shaped skull there is often a want of lateral symmetry of the convolutions. Arising cells (granule-cells) is in part in the topographical relations of convolutions, and have served not a little to puzzle the phrenologist. Thus the artificial division of the Caribus having bulged the squama occupitis, they decided that these were the parts love of men, &c.

1 Neurologisches Centralblatt (1884), p. 429.

3 Centralblatt (1880), No. 14; Beitrag zur Biologie (Stuttgart 1882).

4 Martius tells us that the Caribus castrate their own children, 8. The existence of structural differences between different areas of cerebral cortex is constant to any theory of cerebral localization, but no phrenologist has given as any original information on this point. Since the investigation of J. G. F. Baillarger and Bevan-Lewis it has been shown that some local differentiations of structure within the cortex have been found. Rolando and his ganglion-cells of the fourth layer are of large size (giant-cells of Betz), and in the convolutions of the tempero-sphenoidal lobe larger cell angles are observed, and separated by a distance between the larger pyramidal and the ganglion-cells, so that, while in the part of the brain above the fissure of Sylvius the gray cortex is for the most part five-layered, below and behind that fissure it is six-layered. During the first five years, the only sudden transition of structure of the grey cortex being at the hippocampal sulcus; and giant-cells, although of smaller size, and less like those of the anterior corona of the spinal cord, are scattered over other parts of the cerebral cortex.

Other local variations in structure have been described by Elliott Smith and other histologists.

The teaching of anatomy with regard to phrenology may be summarized thus: (1) the rate of growth of brain is concurrent with the rate of development of mental faculty; (2) there is some degree of structural differentiation as there are varying rates of development of different parts of the cerebral surface; (3) there is no accordance between the regions of Gall and Spurzheim and definite areas of cerebral surface.

Physiological Asclpt.—The theory of some of the older metapl. phrenologists, that the mind, in feeling and reflection, makes use of no material instrument is not now accepted by psychologists. It was advanced by Brougham and Jeffreys as against the theory of phrenology; but the doctrine that the brain is the organ of the mind is now universally receved. While it is probable that certain molecular changes in the grey matter are antecedents or concomitants of mental phenomena, the precise nature of these processes, to what extent they take place, or how they vary among themselves, is not as yet been determined experimentally. The occurrence of the change can only be demonstrated by some such coarse method as the altered pulsation of the carotid arteries, the increase of the temperature of the head, the abstraction, during brain-action, of blood from other organs as shown by the plethysmograph, or the formation of lecitin and other products of metabolism in brain-substance. As yet no light has been shed on the connexion between the molecular changes in the nerve-cell and the phenomena of thought and feeling. While our knowledge of the anatomy of the brain, especially of the grey nuclei and of the white bands uniting them, has in recent years become much more accurate (see articles BRAIN AND MUSCLE AND NERVE, our knowledge of the physiology of the brain has become more and more fragmentary, even when the utmost allowance is made for the researches of C. S. Sherrington, A.S.F. Grünbaum, F. Goltz and others; and the hypotheses relating to the division of labour in the nerve-centres is chiefly based on anatomical structure. Certain masses of grey nerve-matter situated in the spinal cord and medulla oblongata are so linked by nerve-cords to organs outside the nervous system which are set apart for the discharge of separate functions that they obviously form parts of the mechanism for the fulfilment of such functions. In cases where these can be subjected to experiment we learn that they are nervous centres presiding over the discharge of such functions; and it has been determined by experiment, or else deduced from the physiological and anatomical relations of certain nervous centres which are more directly connected with the segmental elements of the body there is a certain localization of function; hence the centres of pelvic actions, of respiration, cardiac action, and inhibition of vasomotor influence, deglutition, secretions, &c., can be mapped out in ascending series. As certain of these centres are united by bands of fibres to the larger fatten and eat them, an abuse of the organ of philoprogenitiveness; see also Garcia de los Vega, Hist. des Insect, i. 12.

PHRENOLOGY

and higher-lying grey portions of the nervous centres there is an a priori presumption in favour of the extension of this principle of localization. This has been premised on metaphysical as well as on anatomical grounds. A. B. Bonnet long ago believed each portion of the brain to have a specifically separate function, and Herbert Spencer has said that "the physiology of the mind requires the conviction that different parts of the cerebrum subserve different kinds of mental action. Localization of function is the law of all organization; separateness of duty is universally accompanied with separateness of structure, and it would be marvellous were an exception to exist in the cerebral hemispheres. Let it be granted that the cerebral hemispheres are the seats of the higher psychical activities; let it be granted that among these higher psychical activities there are distinctions of kind which, though not definite, are yet practically recognizable, and it cannot be denied, without going in direct opposition to established physiological principles, that these more or less distinct kinds of psychical activity must be carried on in more or less distinct parts of the cerebral hemisphere."  

For a masterly review of the old and the new association and localization theories, see W. Wundt's Grundzüge der physiologischen Psychologie, i. 289 sqq.; also the same author's Essays, Leipzig (1888), pp. 109 sqq.

There is a large weight of evidence in favour of the existence of some form of localization of function. So little is known of the physical changes which underlie psychical phenomena, or indeed of the succession of the psychical processes themselves, that we cannot as yet judge as to the nature of the mechanism of these centres. So much of the psychic work of the individual life consists in the interpretation of sensations and the translation of these into motions that there are strong a priori grounds for expecting to find that much of the material of the nervous centres is occupied with this kind of work, but in the present conflict of experimental evidence it is safer to suspend judgment. That these local areas are not centres in the sense of being indispensable parts of their respective motor apparatuses is clear, as the function abolished by ablation of a part returns, though tardily, so that whatever superintendence the removed region exercised apparently becomes assumed by another part of the brain. Experimental physiology and pathology, by suggesting other functions for parts of the brain-surface, are thus directly subversive of many details of the phrenology of Gall and Spurzheim.

Psychological Aspect.—The fundamental hypothesis which underlies phrenology as a system of mental science is that mental phenomena are resolvable into the manifestations of a group of separate faculties. A faculty is defined as "a convenient expression for the particular states into which the mind enters when influenced by particular organs; it is applied to the feelings as well as to the intellect, thus the faculty of benevolence means every mode of benevolence induced by the organ of benevolence" (Combe). In another work the same author says it is "used to denote a particular power of feeling, thinking, perceiving, connected with a particular part of the brain." The assumption is contained in the definition that the exercise of a faculty is the physical outcome of the activity of the organ, and in several of the standard works this is illustrated by misleading analogies between these and other organs; thus the organs of benevolence and of firmness are said to be as distinct as the liver and pancreas. The mind, according to another author, consists of the sum of all the faculties. In this view the unity of consciousness is somewhat difficult to explain, and consequently there is assumed by others a single unifying substratum, and on this the organs are supposed to act; thus thoughts are defined as "relations of the simple substance, mind, to certain portions of the encephalon" (Welsh, Phren. Journ. i. 206). Gall himself believed that there was but a single principal physiologic saw, felt, taste, heat, speech, and called (Fondements du cerveau, i. 243); and the American exponent of phrenology, Caldwell, says "the mind is as single in its power as it is in its substance; it is a quickening and operating principle, essential to all the mental faculties, but does not, by any means, possess them itself" (Elements, p. 16). It is not easy to understand the supposed relation of this hypothetical substratum to the separate faculties acting on it. It must be both immaterial and unconnected with the brain, as the whole two thousand million cells supposed to exist in the cerebral hemispheres are all parcelled out among the faculties, and none are left for the unifying nous.

Each organ is considered as engaged, either independently in bringing forth its own product, or collectively with others in elaborating compound mental states, and according to their several degrees of development and activity they are considered capable of perceiving, conceiving, recollecting, judging or imagining each its own subject. This mechanical conception of the division of labour in the production of the phenomena of mind has the charm of simplicity, but is attended with the difficulty that arises in discriminating the operations of the different organs one from the other. Phrenologists are apt to be vague respecting the limits of the several faculties, as about the boundaries of the separate organs. It was pointed out by Jeffrey that the lines of demarcation between benevolence, adhesiveness and philoprogenitiveness were indeterminate, although the organs are not very close, and the same applies to other organs.

It is unfortunate for the clearness of the definition that, although historically the faculties were the first phenomena noted, independent of and previous to their localization, yet in the definition the faculties are defined in terms of their localities.

The following arguments are adduced in favour of the fundamental separateness of the faculties: (1) analogy—elsewhere in the animal economy division of labour is the rule; (2) the variety of mental endowment observed among children before they are influenced by education, and the inequalities in the mental endowments of individuals; (3) the phenomena of insanity, especially of monomania; (4) the varying periods at which individual faculties attain their maximum development; (5) the phenomena of dreams, and the awakening of a limited number of faculties during them; (6) pain being felt in an organ when it is overtaxed.

Such faculties are supposed to be primary—(1) as exist in savages and not in others, (2) as vary in their development in the sexes, (3) as are developed in varying proportions with regard to other faculties, (4) as may act separately from other faculties, (5) as are not necessarily simultaneous with other faculties in action, (6) as are hereditary, and (7) as may be singly diseased.

According to the development of their powers mankind may be divided into six classes: (1) those in whom the highest qualities are largely developed and the animal qualities feeble; (2) those with the reversed conditions developed, with large animal and feeble intellectual and moral faculties; (3) those in whom good and evil are in constant war, with active animal and strong intellectual faculties and sentiments; (4) those partial geniuses in whom a few qualities are unusually developed, while the rest are at or below the mediocris standard; (5) those men of moderate endowment in whom some faculties are nearly or quite deficient; (6) those with an unvarying standard of undistinguished mediocrity in all their faculties.

It is perhaps unfortunate that the word "faculty" has been used in this sense of original power by phrenologists. It would have been better to employ, as Mr Lewes suggests, the term

1 It is interesting in this connexion to note that in a case published by Professor Hamilton in Brain (April 1884), where a tumour existed in his left lobule, the pain was persistently referred to the forehead. Many similar cases are to be noticed among the records of localized brain-lesions. Bearing on this point also it is worth noting, once for all, that in nothing is the purely hypothetical nature of phrenological description better realized than in the accounts of what these authors call the "natural language of the faculties."—that poets are supposed to touch ideality when composing, musicians to press on tone and time, and painters on form and colour, when in the exercise of their arts! Yet we are greatly taught in this the standard works on the subject.
"function" for the native activity of an organ, and to leave "faculty" for the expression of an acquired activity. "Faculty is properly limited to active power, and therefore is abusively applied to the mere passive affections of the mind" (Hamilton, Lectures, 1. 177).

An attempt has been recently made by Dr. Bernard Holländer to correlate the doctrines of phrenology with the modern physiological and pathological observations which bear upon the localization of the functions of the brain. In his work, The Mental Functions of the Brain, under the sub-title "The Revival of Phrenology" (1901), and in Scientific Phrenology (1902), the author endeavours to bring Gall's clinical and pathological instances into line with more modern observations. He deprecates the craniology of Gall, as far as it deals with mere "bumps," and honours him, with justice, as the recorder of many facts worth saving out of the wreck of his system; and he endeavours, though with doubtful success, to establish an unbroken connexion between phrenology, in the Greek sense, and our present knowledge of cerebral localization.

The substance of Holländer's first work is of two kinds. The one kind is a tabulated statement of many hundred cases of different forms of mania, with injury or disease limited to one portion of the brain; the other kind is a tabulated statement of cases of mania, or disease of the brain, caused by perversive, excitative, or loss of some definite instinct or faculty of consciousness.

He divides the tabulated cases of mania into three groups:

(i) Mania melancholia; (ii) Mania furiosa; and (iii) Mania of the accidents of perjury. For these three groups of cases he lays down the following rules: (i) Manchaelia is especially associated with injury or disease of the parietal lobe of the brain, manifest in the parietal lobe or its convoluted regions. (ii) Mania furiosa is especially associated with injury or disease of the central portion of the temporal lobe. (iii) Mania with suggestion and delusions of persecution is especially associated with injury or disease of the posterior portion of the temporal lobe.

The second kind of cases, where injury or disease of the brain, supposed to be localized to one part or another of its grey matter, was followed by perversion, excitation, or loss of some one instinct, habit, or faculty, includes cases of kloptomania, cases of voracious hunger and thirst, cases of sexual desire, and cases of the most general of all special memories, as of words, tunes, numbers and the like.

These two collections of recorded cases, taken from a vast mass of clinical and pathological literature accumulated during the past century, have been arranged by Dr. Holländer with great industry; so as to extend the limits of the study of cerebral localization, and to advance it from the observation of the motor areas and the special sense centres to the observation of the higher acts and states of consciousness. In this, the negative point of view, is engaged over finer and finer issues of microscopic and experimental work; and, from its subjective point of view, is becoming more and more psychological, seeking a higher level of interpretation, and a more intimate knowledge of the mental life of man, than was ever entertained by the more increasing complexity. The motor centres, governing voluntary movements of the body, are considered to be not simply muscles, but their speech-centres are not homogeneous, but are on experimental grounds differentiated into sub-centres for the utterance of words, the recognition of words, and the understanding of words; the visual centres are like manner subdivided according to the consciousness involved in the complex act of vision. There is room, therefore, for a "higher phrenology," if it can show clear evidence in favour of the localization, in determinate regions of the brain, of the physical changes accompanying changes of mental consciousness.

Of the two kinds of cases that Dr. Holländer has tabulated, it cannot be said that the cases of mania are convincing. Some of them are altogether beside the mark; e.g., he quotes two cases of melancholia, after an injury over the left parietal bone, which were cured by an operation limited to the scalp (excision of a painful scar, removal of a small nerve-tumour of the scalp); in another case of melancholia, the skull was broken, but the patients were cured of their melancholy. Again, the acceptance of these rules as to the localization of these insane thoughts involves the localization of sane thoughts in the same areas of the brain, and the operation of one hemisphere on the other, which is beyond the boundaries of our present knowledge. Moreover, cases of mania are so common that it might be possible to find an equal number of cases to control its rules; we want counter, not picked cases. If 1000 cases of scaphocephaly are examined, and it be found that 999 of these, post mortem record of each case, were tabulated, we should then begin to stand on surer ground. Again, though Dr. Holländer seems to argue well, he may say that the facial and other movements, induced by direct electrical stimulation of certain convolutions are such as express the mental states which he attributes to those convolutions, yet this argument is insecure, partly because Sheringham's work gives the motor area of the face and movements has rendered it necessary to reconsider the present localization of the motor area in man, and partly because the interpretation of facial and muscular movements as representing this or that state of the cerebral or a muscular action is always getting new bases.

The second kind of cases, where injury or disease limited to one portion of the brain is followed by perversion, excitation, or loss of some specific function, is of especial interest. The cases of voracious hunger and thirst, those of true kloptomania, and those of the loss of certain special memories. It is not so easy to believe that the cerebral is in any primary way associated with sexual desire; its position, its structure and its proved association with the co-ordination of muscular movements seem clearly to indicate that its work is wholly subordinate and complementary to the work of the cerebral hemispheres; and the impulses hardly amounts to more than a probability that it may transmit or co-ordinate the performance of the sexual act.

Practical Application.—"Die Schädellähere ist allerdings nicht so sehr Irrthum in der Idee als Charlatanerie in der Ausführung," says one of its most acute critics. Even though no fault could be found with the physiology and psychology of phrenology, it would not necessarily follow that the theory could be utilized as a practical method of reading character; for, although the inner surface of the skull is moulded on the brain, and the outer surface corresponds with it in the same way, the skull itself, being purely angular, is sufficiently variable to render conclusions therefore uncertain. The spongy layer or diploe which separates the two compact tables may vary considerably in amount in different parts of the same skull, as in the cases described by Professor Humphry (Journ. of Anat. vii. 137). The frontal sinus, that opprobrium phrenologicum, is a reality, not uncommonly of large size, and may wholly occupy the regions of five organs. The centres of ossification of the frontal and parietal bones, the muscular cisterns of these and of the occipital bones also, differ in their prominence in different skulls. Premature synostoses of sutures mould the brain without doing much injury to its proper development. The cranium is a structure capable of many directions modifying sometimes to an extreme degree the relation of brain-surface to skull-surface. The writer has found such displacements in extremely sphacophaecal skulls; the same is true of accidental deformations due to pressure on the infantile skull before it consolidates. Artificial malformations alter the apparent skull shape considerably while they affect the relative development of the parts of the brain cortex but little. All these and other cogent reasons of a like kind, whose force can be estimated by those accustomed to deal with the component soft parts of the head, should lead phrenologists to be careful in predicting relative brain-development from skull-shape. The psychology, physiology, and pathalogy of the skull are directly connected with the practical working of the system and to show how worthless the so-called diagnoses of character really are. Its application by those who are its votaries is seldom worse than amusing, but it is capable of doing positive social harm, as in its proposed application to the discrimination or selection of servants and other subordinate officials. It has even been proposed to use it for the purposes of the guarantee society and for the selection of parliamentary representatives. The sarcastic suggestion which originated with Christopher North of moulding children's heads so as to suppress the evil and foster the good was actually repeated in good faith by a writer on physiognomy, but experience of the effects of malformation leads one to be sceptical as to the feasibility of this mode of producing a social Utopia.

PHRYGIA, the name of a large country in Asia Minor, inhabited by a race which the Greeks called Phryges, freemen. Roughly speaking, Phrygia comprised the western part of the great central plateau of Anatolia, extending as far east as the river Haly; but its boundaries were vague, and varied so much at different periods that a sketch of its history must precede any account of the geography. According to unvarying Greek tradition the Phrygians were most closely akin to certain tribes of Macedonia and Thrace; and their near relationship to the Hellenic stock is proved by all that is known of their language and art, and is accepted by almost every modern authority. The country named Phrygia in the better known period of history lies inland, separated from the sea by Paphlagonia, Bithynia, Cappadocia and Cilicia, and occupied by the chief point of the "thalassocracy" at the beginning of the 9th century B.C. The Troad and the district round Mt Sipylos are frequently called Phrygian, as also is the seaport Sinope; and a district on the coast between Sestus and the river Cius was regularly named Little Phrygia; names like Mygdones, Doliones and Phryges or Briges, &c., were widely current both in Asia Minor and in Europe. The inference has been generally drawn that the Phrygians belonged to a stock widespread in the countries which lie round the Aegean Sea. There is, however, no conclusive evidence whether this stock came from the east over Armenia, or was European in origin and crossed the Hellespont into Asia Minor; but modern opinion inclines decidedly to the latter view.

According to Greek tradition there existed in early time a Phrygian kingdom in the Sangarius valley, ruled by kings among whom the names Gordius and Midas were common. It was known to the ancient Greeks of Ionia and the Troad as something great and half-divine. When the goddess appeared to her favourite Anchises she represented herself as daughter of the king of Phrygia; the Phrygians were said to be the oldest people, and their language the original speech of mankind; the Phrygian kings were familiar associates of the gods, and the heroes of the land tried their skill against the gods themselves; we hear of the well-walled cities of Phrygia and of the riches of its kings. Tradition is completely corroborated by archaeological evidence. In the mountainous region on the upper waters of the Sangarius, between Kutaiah Eski Shehr and Afiun (Afion) Kar Hisar, there exist numerous monuments of great antiquity, showing a style of marked individuality, and implying a high degree of artistic skill among the people who produced them. On two of these monuments are engraved the names of "Midas the King" and of the goddess "Kybile the Mother." Even the title "king" (βασιλεύς) appears to have been borrowed by Greek from Phrygian.

It is impossible to fix a date for the beginning of the Phrygian kingdom. It appears to have arisen on the ruins of an older civilization, whose existence is revealed to us only by the few monuments which it has left. These monuments, which are found in Lydia, Phrygia, Cappadocia and Lydia, as well as in north and central Syria, point to the existence of a homogeneous civilization over those countries; they show a singularly marked style of art, and are frequently inscribed with a peculiar kind of hieroglyphics, engraved boustrophedon; and they originated probably from a great Hititte kingdom, whose kings ruled the countries from Lydia to the borders of Egypt. There can be no doubt that in Asia Min an ancient road-system, towards the "royal road" from Sardis to the Persian capital, Susa (Herod. v. 53). The royal road followed a route so difficult and circuitous that it is quite unintelligible as the direct path from any centre in Persia, Assyria or Syria to the west of Asia Minor. It can be understood only by reference to an imperial centre far in the north. The old trade-route from Cappadocia to Sinope, which had passed out of use centuries before the time of Strabo (pp. 450, 456), fixes this centre with precision. It must be far enough west to explain why trade tended to the distant Sinope,4 hardly accessible behind lofty and rugged mountains, and not to Amisos by the short and easy route which was used in the Graeco-Roman period. This road-system, then, points distinctly to a centre in northern Cappadocia near the Haly. Here must have stood the capital of some great empire connected with its extremities, Sardis or Ephesus on the west, Sinope on the north, the Ephorates on the east, the Cilician Gates on the south, by roads so well made as to continue in use for a long time after the centre of power had changed to Assyria, and the old road-system had become circuitous and unsuitable.5 The precise spot on which the city stood is marked by the great ruins of Boghaz Keui, probably the ancient Pteria, of which the wide circuit, powerful walls and wonderful rock-sculptures make the site imitate the most remarkable in Asia Minor. On this site Winckler found in 1907 the records of the Hititte kings who fought against Egypt and Assyria.

The ancient road from Pteria to Sardis crossed the upper Sangarius valley, and its course may be traced by the monuments of this early period. Close to its track, on a lofty plateau which overhangs the Phrygian monument inscribed with the name of "Midas the King," is a great city, inferior indeed to Pteria in extent, but surrounded by rock-sculptures quite as remarkable as those of the Cappadocian city. The plateau is 2 m. in circumference, and presents on all sides a perpendicular face of rock 50 to 200 ft. in height. This natural defence was crowned by a wall partly Cyclopean, partly built of large squared stones. This city was evidently the centre of the old Phrygian kingdom

4 Fovvopa on the Midas tomb. It is expressly recorded that ryovpamos is a Lydian word. Bartsch avoids all attempts to explain it as a purely Greek formation, and the termination assimilates it to certain Phrygian words.

5 Sinope was a Greek colony in 731 B.C., but it is said to have existed long before that time.

6 When the Persians conquered Lydia they retained, at least for a time, this route, which they found in existence.

4 The stones have all fallen, but the line where they were fitted on the rocks can be traced by any careful explorer. The small fortress Phishnsh Kaleesi is a miniature of the great city beside it. (See Perrot, Explor. Archéol. p. 169 and pl. viii.)
of the Sangarius valley, but at least one of the monuments in it seems to belong to the older period of Cappadocian supremacy, and to prove that the city already existed in that earlier time. The Phrygian kingdom and art therefore took the place of an older civilization. It is probable that the tradition of battles between the Phrygians and the Amazons on the banks of the Sangarius preserves the memory of a struggle between the two races and the victory of the Phrygians.

Of the monuments that exist around this city two classes may be confidently referred to the period of Phrygian greatness. That which is inscribed with the name of "Midas the King" is the most remarkable example of one class, in which a large perpendicular surface of rock is covered with a geometrical pattern of squares, and the figures and inscriptions are surmounted by a pediment supported in the centre by a pilaster in low relief. In some cases a floral pattern occupies part of the surface, and in one case the two sides of the pediment are filled by two sphinxes of archaic type. In some of these monuments a doorway is carved in the lower part; the door is usually closed, but in one case, viz. the sphinx monument just alluded to, the valves of the door are thrown wide open and give access to a little chamber, on the back of which is sculptured in relief a rude image of the Mother-goddess Cybele, having on each side of her a lion which rests its forepaws on her shoulder and places its head against her breast. The head of another lion has been found hidden behind the head and body of the goddess, but no further south of the Ionian city of Phokaia, the little town of Phrygian foundation, the city of the Phrygians in the interior of Asia Minor, is the mother of the capital city of Phrygia. The name of Phrygia is derived from Phrygian, the chief of the Phrygian tribes. The Phrygian alphabet was carried to Phrygia and Pteria, either from Sipylus or more probably direct east from Cyme, in the latter part of the 8th century. The influence of the Phrygian alphabet and art upon the Ionians is evident throughout the Ionian world. The Phrygian alphabet was carried to Phrygia and Pteria, either from Sipylus or more probably direct east from Cyme, in the latter part of the 8th century. complete success, till some time between 610 and 590 B.C. Phrygia then fell under the Lydian power, and by the treaty of 585 B.C. the Halys was definitely fixed as the boundary between Lydia and Media (see Lydia and Persia). The period from 595 to 585 B.C. must therefore be considered as one of great disturbance and probably of complete paralysis in Phrygia. After 585 B.C. the country was ruled again by its own princes under subjection to Lydia supremacy. To judge from the monuments, it appears to have recovered some of its old prosperity; but the art of this later period has to a great extent lost the strongly marked individuality of its earlier bloom. The later sepulchral monuments belong to a class which is widely spread over Asia Minor from Lydia to Pontus. The graves are made inside a chamber excavated in the rock, and the front of the chamber imitates a house or temple. No attempt is made to conceal the entrance or to render it inaccessible. The architectural details are in some cases unmistakably copied, without intentional modification, from the architecture of Greek temples; others point perhaps to Persian influence, while several—which are perhaps among the early works of this period—show the old freedom and power of employing in new and original ways details partly learned from abroad. This style continued in use under the Persians, under whose rule the Phrygians passed when Cyrus defeated Croesus in 546, and lasted till the Roman period. One monument appears to presuppose a development of Greek plastic art later than the time of Alexander and is almost certainly of the Roman time. It would, however, be wrong to suppose that the influence of truly Hellenic art on Phrygia began with the conquest of Alexander. Under the later Mermnad kings the Lydian empire was penetrated with Greek influence, and Xanthus, the early Lydian historian, wrote his history in Greek. Under the Persian rule perhaps it was more difficult for Greek manners to spread far east; but we need not think that European influence was absolutely unfelt even in Phrygia. The probability is that Alexander found in all the large cities a Greek foot. The Phrygian name in this period is first described by Strabo, and much is to be learned from the ancient writers with regard to the state of Phrygia from 585 to 500 B.C. The slave-trade flourished. The Phrygian slaves were common in the Greek market, and the Phrygian names Midas and Manes were stock-names for slaves. Herodotus (i. 14) records that a king Midas of Phrygia dedicated his own chair at Delphi; the chair stood in the treasury of Cypselus, and cannot have been deposited there before 680 to 660 B.C. It is not improbable that the event belongs to the time of Alyattes or Croesus, when Greek influence was favoured throughout the Lydian empire; and it is easy to understand how the offering of a king Midas should be considered, in the time of Herodotus, as the earliest made by a foreign prince to a Greek god. The Phrygian names in the army of Xerxes were armed like the Armenians and led by the same commander.

It is to be presumed that the cities of the Sangarius valley gradually lost importance in the Persian period. The final catastrophe was the invasion of the Gauls about 270 to 250 B.C. and, though the circumstances of this invasion are almost unknown, yet we may safely reckon among them the complete devastation of northern Phrygia. At last Attalus I., settled the Gauls permanently in eastern Phrygia, and a large part of the country was henceforth known as Galatia. Strabo mentions that the cities of ancient Phrygia were in his time either deserted or marked by mere villages. The great city over the tomb of Midas has remained uninhabited down to the present day. About 5 m. west of it, near the modern Kumbet, stood Metropolis, a bishopric in the Byzantine time, but never mentioned under the Roman empire. Alexander the Great placed Phrygia under the command of Antigonos, who retained it when the empire was broken up. When Antigonos was defeated and slain, at the decisive battle of Ipsus, Phrygia came under the sway of Seleucus. As the Pergamenian kings grew powerful, and at last confined the Gauls in eastern Phrygia, the western half of the country was incorporated in the kingdom of Pergamum. Under the Roman empire Phrygia had no political existence under a separate government, but formed part of the vast province of Asia. In autumn 85 B.C. the pacification of the province was completed by Sulla, and throughout the imperial time it was common for the Phrygians to date from this era. The imperial rule was highly favourable to the spread of Hellenistic civilization, which under the Greek kings had affected only a few of the great cities, leaving the mass of the country purely Phrygian. A good deal of local self-government was permitted; the cities struck their own bronze coins, inscribed on them the names of their own magistrates, and probably administered their own affairs matters purely local. The western part of the country was pervaded by Graeco-Roman civilization much sooner than the central, and in the country districts the Phrygian language continued in common use at least as late as the third century after Christ.

When the Roman empire was reorganized by Diocletian at the end of the 3rd century Phrygia was divided into two provinces, distinguished at first as Prima and Secunda, or Great and Little, for which the names Pacatiana and Salutaris soon came into general use. Pacatiana comprised the western half, which had long been completely pervaded by Graeco-Roman manners, and Salutaris the eastern, in which the native manners and language were still not extinct. Each province was governed by a procurator about A.D. 412, but shortly after this date an officer of consular rank was sent to each province (Hierocles, Synedra). About 535 Justinian made some changes in the provincial administration: the governor of Pacatiana was henceforth acomes, while Salutaris was still ruled by a consularis. When the provinces of the Eastern empire were reorganized and divided into themata the two Phrygias were broken up between the Anatolic, Opsician, and Thracian themes, and the name Phrygia finally disappeared. Almost the whole of Byzantine Phrygia is now included in the vilayet of Brusz with the exception of a small part of Paros and the district about Themisionum (Karayuk Bazar) and Ceretaps (Kayadibi), which belong to the vilayet of Konia, and the district of Laodicea and Hierapolis, which belongs to Aïdin. The principal modern cities are Kutahia (Cotyaeum), Eski Shehri (Dorylaeum), Afom Kara Hisar (near Pamnnessus), and Ushak (Trajanopolis).

It is impossible to say anything definite about the boundaries of Phrygia before the 5th century. Under the Persians Great Phrygia extended on the east to the Halys and the Salt Desert; Xenophon (Anab. i. 2, 19) includes Ionia on the southeast within the province, whereas Strabo makes Tyriacum the boundary in this direction. The southern frontier is unknown: the language of Lügy (xxxvii. 13) implies that the southern frontier was the River Kus (in the Tchul Ova) helped by Pidisia; but Strabo (p. 629) includes it in Phrygia. Celaenea, beside the later city of Apamea (Dineire), and the entire valley of the Lycus, were Phrygian. The Maeander above its junction with the Lycus formed for a little way the boundary between Phrygia and Lydia. The great plateau now called the Banaz Ova was entirely or in great part Phrygian. Mt Dindymus (Murad Dağ) marked the frontier of My西亚, and the entire valley of the Temborius or Tembris (Porsuk Su) was certainly included in Phrygia. The boundaries of the two Byzantine Phrygias were not always the same.

Taking Hierocles as authority, the extent of the two provinces at the beginning of the 6th century will be readily gathered from the accompanying list, in which those towns which coined money under the Roman empire are italicized and the name of the nearest modern village is appended.

1. PACATINA.—(1) Laodicea (Eski Hisar); (2) Hierapolis (Pambuk Kalesi); (3) Mosyna (Gevze); (4) Motebolis, only in Notitia

This list was not granted to the cities of any other province in Anatolia.

A number of inscriptions in a language presumably Phrygian have been discovered in the centre and east of the country; they belong generally to the end of the 3rd and to the 3rd century.

Phrygia contains several well-marked geographical districts.

(1) PARABUS, the long, level, elevated valley stretching north-west from south-east between the Soltan (or Dogus) and the Euphrates (from Hevaz to Tchali) to Tyrisium (Ilim); its waters collect within the valley, in three lakes, which probably supply the great fountains in the Axylon and through them the Sangarius. (2) AXYLON, has a supply of water from the upper Euphrates, at various points great perennial springs, the Sakaria fountains (Strabo p. 545), Ilje Bashi, Bunur Bashi, Geuk Burn, Buzuk Bashi, &c., which feed the Sangarius. Great part of the Axylon was assigned to Galatia. (3) The rest of Phrygia is mountainous (except the great plateau, Banaz Ova), consisting of hill-country intersected by rivers, each of which flows through a fertile valley of varying breadth. The northern half is drained by rivers running northward, from the Tchali (Tembrogus) to the Tchali (Tembrogus), Seidei Sur (Partenius), Bardakchi Tchali (Xerabates), and Bayat Tchali (Alanidrus), join the Sangarius, while the western, 2 Tavar, flows into the Catras. The great river in the interior, which flows from Messivity and thence into the Procopion. The Hermus drains a small district included in the Byzantine Phrygia, but in earlier times assigned to Lydia and Mysia. Great part of southern and western Phrygia is waterless: high mountains with scarce vegetation, and pastures and Grapes, which still grow abundantly in various parts, were much cultivated in ancient times. Other fruits are rare, except in a few small districts. Figs cannot be grown in the country, and the ancient Phrygians were compelled to use the loose term of the Phrygia. 3 Trees are exceedingly scarce in the country; and the pine-woods on the western tributaries of the Sangarius and the valonia oaks in parts of the Banaz Ova and a few other districts of the country. The unadaptability of the country to agriculture is probably why the ancient Phrygians were compelled to use the term of the Zima district, north of Iconium. The scenery is generally monotonous; even the mountainous districts rarely show striking features.

No. 1-5 were called the Phrygian "Pentapolis." 1

1 This district was according to the Greek view part of Mysia.

2 In Strabo, p. 577, "doros" is written; or "menos" is the word, and is probably the right reading. Olives cannot now grow on these uplands, which are more than 3000 ft. above sea-level.

PHRYNE, Greek courtesan, lived in the 4th century B.C. Her real name was Mnesarete, but owing to her complexion she was called Phryne (toid), a name given to other courtesans. She was born at Theopse in Boeotia, but owing to her complexion she was called Phryne (toid), a name given to other courtesans.

She acquired so much wealth by her extraordinary beauty that she offered to rebuild the walls of Thebes, which had been destroyed by Alexander the Great (336), on condition that the words " Destroyed by Alexander, restored by Phryne the courtesan," were inscribed upon them. On the occasion of a festival of Poseidon at Eleusis she laid aside her garments, let down her hair, and stepped into the sea in the sight of the people, thus suggesting to the painter Apelles his great picture of Aphrodite Anadyomene, for which Phryne sat as model. She was also (according to some) the model for the statue of the Cnidian Aphrodite by Praxiteles. When accused of profaning the Eleusinian mysteries, she was defended by the orator Hypereides, one of her lovers. When it seemed as if the verdict would be unfavourable, he rent her robe and displayed her lovely bosom, which so moved her judges that they acquitted her. According to others, she herself thus displayed her charms. She is said to have made an attempt on the virtue of the philosopher Xenocrates. A statue of Phryne, the work of Praxiteles, was placed in a temple at Theopse by the side of a statue of Aphrodite by the same artist.

See Athenaeus, pp. 52b, 56a, 58a, 58b, 59a, 59b; *Aelian, Var. Hist.,* viii. 7; *Plutarch, Mor.,* xxxiv, 71.

PHRYNICHUS—1. Son of Polyphræmon and pupil of Thespis, one of the earliest of the Greek tragedians. Some of the ancients, indeed, regarded him as the real founder of tragedy. He gained his first poetical victory in 511 B.C. His famous play, the *Capture of Miletus,* was probably composed shortly after the conquest of that city by the Persians. The audience was moved to tears, the poet was fined for reminding the Athenians of their misfortunes, and it was decreed that no play on the subject should be produced again. In 476 Phrynichus was successful with the *Phoenseis,* so called from the Phoenician woman who formed the chorus, which celebrated the defeat of Xerxes at Salamis (480). Thermistocles acted as chorus, and one of the objects of the play was to remind the Athenians of his great deeds. The *Persians of Aeschylus* (472) was an imitation of the *Phoenseis.* Phrynichus is said to have died in Sicily. Some of the titles of his plays, *Danadizes, Actaeon, Alectris, Tantalus,* show that he treated mythological as well as contemporary subjects. He introduced a separate actor as distinct from the leader of the chorus, and thus laid the foundation of dialogue. But in his plays, as in the early tragedies generally, the dramatic element was subordinate to the lyric element as represented by the chorus and the dance. According to Suidas, Phrynichus first introduced female characters on the stage (played by men in masks), and made special use of the trochaic tetrameter.

Fragments in A. Nauck, *Tragicorum graecorum fragmenta* (1887).

2. A poet of the Old Attic comedy and a contemporary of Aristophanes. His first comedy was exhibited in 429 B.C. He composed ten plays, of which the *Solitary* (Μόνοςοι) was exhibited in 414 along with the *Birds* of Aristophanes and gained the third prize. The *Muses* carried off the second prize in 405. Aristophanes being first with the *Frogs,* in which he accuses Phrynichus of employing vulgar tricks to raise a laugh, of plagiarism and bad versification.

Fragments in *T. Kock, Com二人orium aliacorum fragmenta* (1880).

3. PHRYNICHUS ARABUS, a grammarian of Bithynia, lived in the 2nd century A.D. According to Suidas he was the author of (1) an *Atticis,* or *On Attic Words,* in two books; (2) Τιμούμενα συναγεργη, a collection of subjects for discussion; (3) Συμμονή παρασκευή, or Sophistical Equipment, in forty-seven (or seventy-four) books. As models of Attic style Phrynichus assigned the highest place to Plato, Demosthenes and Aeschines the Sophistic. The work was learned, but prolix and garrulous. A fragment contained in a Paris MS was published by B. de Montfaucon, and by I. Bekker in his *Anecdota Graeca* (1814). Another work of Phrynichus, not mentioned by Photius, but perhaps identical with the *Atticis* mentioned by Suidas, the *Selection* (Εκλεγη) of Attic Words and Phrases, is extant. It is dedicated to Cornelian, a man of literary tastes, and one of the imperial secretaries, who had invited the author to undertake the work. It is a collection of current words and forms which deviated from the Old Attic standard, the true Attic equivalents being given side by side. The work is thus a lexicon anti-barbarum, and is interesting as illustrating the changes through which the Greek language had passed between the 4th century B.C. and the 2nd century A.D.

Editions of the *Εκλεγη* with valuable notes, have been published by C. A. Lobecq (1820) and W. G. Rutherford (1881); Lobecq devotes his attention chiefly to the later, Rutherford to the earlier usages noticed by Phrynichus. See also J. Brennon, *De Phrynico Atticis* (1895).

4. An Athenian general in the Peloponnesian War. He took a leading part in establishing the oligarchy of the Four Hundred at Athens in 411 B.C., and was assassinated in the same year (Thucydidès viii.).

PHTHALAZINES (benzo-orthodiazines or benzopyridazines), in organic chemistry a group of heterocyclic compounds containing the ring complex shown in formula I. They are isomeric with the cinnolines (q.v.). The parent substance of the group, phthalazine, C₄H₄N₂, is best obtained from the condensation of α-tetrachloromethylenone with hydrazine (D. Gabriel, *Ber.,* 1893, 26, p. 2210), or by the reduction of chlorophthalazine with phosphorus and hydriodic acid (Ber., 1897, p. 3024). It possesses basic properties and forms addition products with alkyl iodides. On oxidation with alkaline potassium permanganate it yields pyridazine dicarboxylic acid. Zinc and hydrochloric acid decompose it with formation of orthoxylylene diamine. The keto-hydro derivative phthalasone, C₄H₄O₂N₂, (formula II.), is obtained by condensing phthalaldehydehydroazoic acid with phosphorus oxychloride in pyridine. Phthalazine which with zinc and hydrochloric acid gives isoidole, C₄H₄N, and with tin and hydrochloric acid phthalimidine, C₄H₄ON, the second nitrogen atom being eliminated as ammonia.

```
\[ \text{I. Phthalazine  II. Phthalazone} \]
```

PHTHALIC ACIDS, or BENZENE DICARBOXYLIC ACIDS, C₄H₄(OH)₂. There are three isomers: (1) ortho, or phthalic acid; (2) meta, or isophthalic acid; (3) para, or terephthalic acid.

Phthalic acid was obtained by Laurent in 1836 by oxidizing naphthalene tetrachloride, and, believing it to be a naphthelene derivative, he named it naphthalene acid; Marignac determined its formula and showed Laurent's supposition to be incorrect, upon which Laurent gave it its present name. It is manufactured by oxidizing naphthalene tetrachloride (prepared from naphthalene, potassium, chlorine and hydrochloric acid) with nitric acid, or, better, by oxidizing the hydrocarbon with fuming sulphuric acid, using mercury or mercuric sulphate as a catalyst (German pat. 91, 220). It also results from the oxidation of ortho-
dierivatives of benzene. It forms white crystals, melting at 273° with decomposition into water and phthalic anhydride; the latter forms long white needles, melting at 128° and boiling at 198°. Heated with an excess of lime it gives benzene; calcium benzoate results when calcium phthalate is heated with one molecule of lime to 330°-350°. The acid (and anhydride) are largely used in the colour industry (see Fluorescein; Phenolphthalein).

Phthalimide, C₆H₄(COCl)₂ or C₆H₄(Cl)₂(CO)O, formed by heating the anhydride with phosphorus chloride, is an oil which solidifies at 0° and boils at 275°. In some reactions it behaves as having the first formula, in others as having the second. Phthalimide with phosphorus pentachloride gives two phthalylene tetrachlorides, one melting at 88° and the other at 47°. They cannot be changed into one another, and have been given the formulæ C₆H₄(CCl₄)₂ and C₆H₄(Cl)₂(CO). Phthalimide, C₆H₄(COCl)₂NH, is formed by heating phthalic anhydride or chloride in ammonia gas or by molecular rearrangement of ortho-cyanobenzoic acid. It forms N-metallalic and alkyl salts. Bromine and potash give antrhanic acid, C₆H₄(NH₂)₂(CO)₂H. (See Indigo.)

isophthalic acid is obtained by oxidizing meta-xylene with chromic acid, or by fusing potassium meta-sulphobenzonate, or meta-bromobenzonate with potassium formate (terephthalic acid is also formed in the last case). It melts above 300°, and dissolves in 7800 parts of cold water and in 460 of boiling. The barium salt (4H₂O) is very soluble (a distinction between phthalic and terephthalic acids). Uvic acid, 5-methyl isophthalic acid, is obtained by oxidizing mesitylene or by condensing pyroracemic acids with barium chlorate. Terephthalic acid, formed by oxidizing para-dierivatives of benzene, or best by oxidizing caraway oil, a mixture of cymene and cuminol, with chromic acid, as almost insoluble in water, alcohol and ether; it sublimes without melting when heated.

For the reduced phthalic acids see Poly methylene.

PHTHISIS (Gr. φθίσης "wasting"), a term formerly applied (like "Consumption") to the disease of the lung now known as Tuberculosis (q.v.).

PHYLACTERY (φύλακτηρ, a Greek word meaning "guard" (e.g. against misfortune), i.e. an amulet. It is applied in the New Testament to the tefillin or "prayer-thongs" worn by orthodox Jews daily at morning-prayer (whether at home or in the synagogue). The title employed in Hebrew, tefillin, seems readily to be derived from an Aramaic term meaning "attachments," "ornaments"; it corresponds to the Biblical Hebrew word rendered "frontlets" (תָּלָשׁ). The tefillin or phylacteries are worn, one on the left arm (the "hand-tefilla"), and the other on the head (the "head-tefilla"). In each case the leather thongs support a small satchel which is fastened to the arm and the forehead respectively, and contains certain passages of the Law written (in Hebrew) on parchment, viz. Exod. xiii 1-10 and i 16; Deut. vi. 4-9 and xi. 13-21. The custom of wearing phylacteries seems to have been derived in the first instance from the Pharisees. By the Sadducees and the generality of the people in the time of Christ it seems not to have been practiced. Later it became not without protest one of the badges of orthodox Judaism. It is significant that the custom is entirely unknown to the Samaritan community.

The phylacteries, together with the "fringe" (tsittas) and door-post symbol (mezuza)—which latter consists of a piece of parchment, containing the Hebrew text of Deut. vi. 4-9 and xi. 13-21 enclosed in a glass or metal tube, and fixed upon the right hand post of the door of each dwelling-room in a house—form the three sets of visible signs by which the Israelite is constantly reminded of his duty to God (cf. Num. xv. 39-40; Deut. vi. 9; xi. 20). The "fringe" (or "tassels") was originally attached to the common outer garment—a large square wrap—the loose end of which hung over the left shoulder. This garment with tassels is mentioned in the New Testament (cf. Matt. 23:5; Matt. 5:39; xiv. 36; xxii. 5 and parallels). Among modern Jews it has survived in two forms: (1) the fringed praying shawl called talit worn by every male orthodox Jew at the synagogue morning service; and (2) an under-garment, shaped like a chest-protector, one part covering the chest, the other the back, which is worn continuously by male orthodox Jews. It is called Arba Kanfoth (i.e. "Four Corners," Deut. xxii. 12) or "little Talith," and is, of course, "fringed." Both phylactery and mezuzah were supposed to keep off hurtful demons (Targ. on Cant. viii. 3).

See Surenhusius, Mischna, i. 9 seq.; and Bodenschutz, Kirch. Verf. d. heutigen Juden, iv. 9 seq. (W. R. S.; G. H. Bo.)

PHYLARCHUS, a Greek historian, who flourished during the time of Aratus, the strategus of the Iberian League, in the 3rd century, so often seen having his birthplace variously given as Athens, Naucratis, or Sicilyon. He was probably a native of Naucratis, and subsequently migrated to Athens. He was the author of a history in 28 books, covering the period from the expedition of Pyrrhus king of Epirus to Peloponnesus (272) to the death of the Spartan king Cleomenes (220) after his defeat by Antigonus Doson. Polybius (ii. 56-63) charges him with undue partiality for Cleomenes and unfairness towards Aratus; Plutarch (Aratus, 38), who is of the same opinion, did not hesitate to use him freely in his own biographies of Agis and Cleomenes.

Fragments and life by C. W. Müller, Aegypten historiorum fragmenta, vol. i. (1841); reprinted by J. F. Luecht (1856) and C. A. F. Brücker (1839); C. Wachsmuth, Einleitung in das Studium der alten Geschichte (1853).

PHYLE, a mountain fortress, on a pass leading from Athens to Boeotia and Thebes, and commanding a fine view of the Attic plain. It is situated on the south-west end of Mt. Parnes. It is chiefly famous for its occupation by Thrasybulus at the head of the Athenian exiles during the rule of the Thespian tyrant, about 404 B.C. After defending himself from attack, with the help of a snowstorm, he succeeded by a venturesome night march in seizing Munychia. Close to Phyle is the cliff called Harmo, over which the Pythian lightnings were watched for from Athens.

PHYLITE (Gr. φύλλον, a leaf, probably because they yield leaf-like plates, owing to their fissility), in petrology, a group of rocks which are in practically all cases metamorphosed argillaceous sediments, consisting essentially of quartz, chlorite and muscovite, and possessing a well-marked parallel arrangement or schistosity. They form an intermediate term in the series of altered clays or shaly deposits between clay-slates and phyllites. Many clay-slates have a very similar chemical constitution to the phylites, but are finer grained and are distinguished also by a very much better cleavage. In the phylites also white mica (muscovite or sericite) is more abundant as a rule than in slate, and its crystalline plates are larger; the abundance of mica gives these rocks a glossy sheen on the smooth planes of fissility. Many of the best Welsh slates are rich in small scales of white mica, which polarize brightly between crossed nics. The Cornish slates are still more micaceous and rather coarser grained, so that they might be called mica-slates or even phylites.

A microscopical section of a typical phylite shows green chlorite and colourless mica both in irregular plates disposed in parallel order, with a greater or smaller amount of quartz which forms small lenticular grains elongated parallel to the foliation. Grains of iron (hematite and haematite) and black graphic dust are very commonly present. Few carborundum is absent or scarce, but some phylites are characterized by the development of small rounded grains of albite, often in considerable numbers. The minute needles of talc, which sometimes seem to be seen as grains of sericite, are not often met with in phylites, but this mineral forms small prisms which may be intergrown with black magnetite; at other times it occurs as networks of sagneite. Other phylites contain carbonate (usually calcite but sometimes dolomite) of flat or splintery habit, or a lamellar variety, as a piece of crushing. Very tiny blue needles of tourmaline are by no means rare in phylites, though readily overlooked. Garnet occurs sometimes, a good example of garnetiferous phylite being furnished by phylites from the South Wales carboniferous district in which there are many small isotropic crystals of magnesian garnet. Hornblende, often in branching feathery crystals, is a less frequent accessory. In some phylites a mineral of the chloritoid group makes its appearance; and in others quartz, albite, muscovite or other varieties of chlorite, and occurs in large sub-hexagonal plates showing complex twinning, and lying across the foliation planes of the rock, so that they seem to have developed after the movements and pressures which gave rise to the foliation had ceased.
The structural variations presented by the phylitse are comparatively few. The most finely crystalline specimens have generally the most perfect and regular arrangement of their constituents. The foliation is generally flat or linear, but in some rocks it is undulate or crumpled. From the imperfection of their cleavage phylitse are rarely suitable for roofing materials; their softness renders them valueless as road stones, but they are not uncommonly employed as inferior building materials. They are among the most widely common in all parts of the world where metamorphic rocks occur; as in the Scottish Highlands, Cornwall, Anglesey, north-west Ireland, the Ardenches on the Alps, Norway, the Appalachians, the Great Lakes district in America, &c. (J. S. F.)

PHYLLOXERA (Gr. φυλλοξερα, leaf, and ἤρπες, dry), a genus of insects belonging to the family of Aphidac, or Plant-lidge, in the Homopterous order of the section of the Hemiptera. It is chiefly known from the causal relation of one of its species to the most serious of vine diseases. The name was first given in 1834 to a plant-louse which was observed to "dry up the leaves" of oaks in the lapse of six. About twelve days, according to the temperature, the larvae hatch out of the eggs. These are light yellow in colour and fleshy; but as they grow older they become brown or black and wither, and the roots on which these swellings occur examined with the lens, a number of minute insects of a yellow-brown colour are observed; these are the root-forms (radicola) of Phylloxera (fig. 1); they are about 8 diam. long, of an oval outline and with a swollen body. When the distinction, the head, thorax and abdomen can be observed. The head bears small red eyes and a pair of three-jointed antennae, the first two joints being short and thick, the third more elongated, with the end cut off obliquely and slightly hollowed out. Underneath, between the legs, lies the rostrum, which reaches back to the abdomen. The insect is fixed by this rostrum, which is inserted into the root of the vine for the purpose of sucking the sap. The abdomen consists of seven segments, and these as well as the anterior segments bear four rows of small tubercles or punctations on their dorsal surface. These root-dwelling insects are females, which lay parthenogenetic eggs. The insect is fixed by its proboscis, but moves its abdomen about and lays thirty to forty yellow eggs in small clusters. After the eggs have been laid, they have selected a convenient place on the young roots, insert their proboscis and become stationary. They moult five times, becoming with each change of skin darker in colour; in about three weeks they become adult and capable of laying parthenogenetic eggs. In this way the insect, in connexion with the temperature and rainfall, it has been calculated that a single mother which dies after laying her eggs in March would have over 25,000,000 descendants by October. If, however, the insect were content with this method of reproduction the disease could be isolated by surrounding the infected patches with a deep ditch full of some such substance as coal-tar, which would prevent the insects spreading on to the roots of healthy vines. The fertility of the parthenogenetically produced insects is also increased after a certain age of generations had been produced.

As the summer wears on a second form of insect appears amongst the root-infesting forms, though hatched from the same eggs as the form described above. These are the nymphs, destined to acquire wings; their body is more slender in outline, and at first they bear well-marked tubercles. After several moult the rudiments of the wings appear, and then the insect creeps up to the surface of the earth, and on to the vine. Here it undergoes its fifth and last moult, and appears as a winged female, capable of reproducing parthenogenetically. The winged form has a slender body with distinct head (fig. 2). The eyes are well developed, with numerous facets; the antennae have three joints, the terminal one shaped like that of the root-dwellers. The wings are transparent, with few nervures, and are well adapted for flight. The anterior pair reach far beyond the end of the abdomen; the posterior are narrower and not so long. These winged forms are about 1 mm. long. They fly about from July till October, living upon the sap of the vine, which is sucked up by the rostrum from the leaves or buds. They lay their parthenogenetically produced eggs in the angles of the veins of the leaves, in the buds, or, if the season is already far advanced, in the bark. In very damp or cold weather the insect remains in the ground near the surface, and deposits its eggs there. The eggs are very few in number and of two sizes, small and large (fig. 3, b and c). From the larger a female (fig. 4) is hatched in eight or ten days, and simultaneously, for the first time in the life-history of the Phylloxera, a male (fig. 3) appears from the smaller egg. Neither male nor female has wings; the rostrum is replaced by a functionless tubercle; and there is no alimentary canal. The male is larger than the female, and differs from it and the other forms in the last joint of the antennae. The life of these sexual forms lasts but a few days, and is entirely taken up with reproduction. The female is fertilized by the male and three or four days later lays a single egg—the winter egg—and then dies. This egg is laid in the crevices of the bark of the vine, and as it is protectively coloured it is almost impossible to find it. Here the winter eggs remain undeveloped during the cold months; but in the following spring, as a rule in the month of April, they give rise to a female insect without wings, which resembles the root-dwelling forms, but has pointed antennae. These forms are termed the stock-mothers; they creep into the buds of the vine, and, as these develop into the young leaves, insert their proboscis into the under side. By this means a gall is produced on the under side of the leaf.

Scheme of the Various Forms of Phylloxera vastatrix.
A. Root-infesting forms, "
B. Root-infesting forms, 2nd generation, "
C. Root-infesting forms, 3rd generation, "
D. Winged forms, "
E. Wingless female, "
F. Male, "
G. Winter egg, "
H. Stock-mother, "
I. Gall-producing, "
J. Root-infesting, "
K. ditto A.

The gall is cup-shaped, and its outer surface is crumpled and covered with small warts and hairs. The opening upon the upper surface
of the leaf is protected by similar structures. Within this gall the stock-mother lives and surrounds herself with numerous parthenogenetically produced eggs—sometimes as many as two hundred in a single gall; these eggs give rise in the space of six or eight days to numerous young, which, some of which form new galls and multiply in the leaves, whilst others descend to the roots and become the root-dwelling forms already described. The galls and the gall-producing form are much commoner in America than in the Old World.

The particular species of phylloxera which attacks the vine is a native of the United States, probably originating among the wild vines of the Colorado district. It was first observed in 1856 by Asa Fitch (1809-1878), who did not suspect its mischief, and called it 

Peporphus vitifoliae. In 1863 it was independently discovered by Westwood in an English vineyard at Hammersmith, where he was ignorant of Fitch's observation, and called it Perthphaeria vitisana. From 1858 to 1883 there were many importations of American vines for grafting purposes to Bordeaux, Roque- maure and other parts of France, England, Ireland, Germany, Portugal, &c. It is practically certain that the deadly phylloxera was imported into these plants. A year or two later certain vine-growers in the South of France began to complain of the new vine-disease. M. Delorme, of Arles, in 1865, appears to have been the first who recognized its novelty and had a presentiment of disaster. The disease steadily spread outwards in concentric circles from its first place of lodgment near Roquemaure. Within two or three years whole departments were infested. In 1866 a second centre of infection made its appearance near Bordeaux. The vine-growers were at their wits' ends with this new plague, which threatened to be even more costly than the oidium. The completeness of the ruin which threatened them may be illustrated by the statistics for a single commune, that of Graveson, whose average annual production of wine in the years 1865-1867 was about 220,000 gallons. In 1868 this fell to 121,000 gallons, in 1869 to 48,400 gallons, in 1870 to 8800 gallons, and by 1873 to 1100 gallons.

In 1868 Plançon proved that the disease was due to a new species of phylloxera, which was invariably found on the roots of the affected vines, and to which he accordingly gave the prophetic name of Phylloxera vastatrix. During the next ten years a series of students, of whom only Riley and Ballani need be mentioned here, worked out the natural history of Phylloxera vastatrix, and proved its identity with the American grape-louse. Its devastations rapidly assumed gigantic proportions. In France, where the disease was by far the most prevalent—owing in great part to the obstinacy with which the vine-growers at first refused to take any reasonable precautions against its spread—M. Lalande, president of the chamber of commerce at Bordeaux, in 1888 calculated the direct loss to the country by the phylloxera at 10 milliards (£400,000,000), or double the indemnity which had been paid to Germany in 1871.

The phylloxera has made its appearance in almost every vine-growing country in the world. Thus it appeared in Austria and Hungary in 1868; in Italy, in spite of the frantic efforts made—as in other countries—to keep it out by strict legislation against the import of vines, in 1879; in Russia in 1880; in Germany, on the Rhine and Moselle, and in Switzerland in 1872; in Madeira, Spain, and Portugal, about the same time. It has even crossed the oceans, and appeared in Australia, at Geelong, about 1880; it has since twice broken out in Victoria, and has ravaged the vineyards of South Australia and New South Wales, in spite of a long-enduring importation of the phylloxera. In South America, where the import of the phylloxera, it appeared about 1884. In 1885 it crossed the Mediterranean to Algeria. There was only one other country in which its ravages were long unimportant; that was the home of the United States, where the native vines have become, by the operation of natural selection, immune to its attacks. Yet no imported vine has ever lived there more than five years, and in 1890 the phylloxera crossed the Rocky Mountains, and seriously damaged the vineyards of California, where it had previously been unknown.

Three different methods of fighting the pest have been successfully adopted. One is to kill the phylloxera itself; another, to destroy it along with the infected vines, and plant fresh and healthy plants; the third, to adapt the secular therapeutics of nature, and to introduce American vines which have a long acquaintance with the phylloxera, and have made hardy, to its ravages, Insecticides, of which the bisulphide of carbon (CS) and the sulpho-carbonate of potassium (KSCS) remain in use, were injected into the earth to kill the phylloxera on the roots of the vine.

These methods were chiefly advocated in vineyards of the first class, where it was worth while to spend a good deal of money and labour to preserve the old and famous vines: the Château Leoville Poyferré and Clos Vougeot are instances. Some good judges attribute the peculiar and not unpleasing flavour of certain clarets to the phylloxera. The second plan was largely adopted in Switzerland and on the Rhine, where measures resembling those taken with cattle suspected of anthrax were applied to all diseased vineyards. The third plan, which consists in replanting the affected vineyard with American vines—such as the Vitis labrusca, V. riparia, V. rupestris or V. monticola—has proved the most generally successful.

A very good bibliography will be found in Les Insectes de la vigne, by Professeur Majet of Montpellier (1890), which is the best book on the subject. Reference may also be made to the classic memoirs of Plançon, published in Les Mœurs de la phylloxera de la vigne (1877); Dreyfus, Uber Phylloxerinen (1886); Lichtenstein, Histoire du phylloxera; les Rapports annuels a la commission de phylloxera, and the excellent Report on Phylloxera drawn up by the Hon. J. W. Tavener (Victoria, 1890, No. 68).

(W. E. F. G.)

PHYSHARMONICA, a keyboard instrument fitted with free-reeds, a kind of harmonium much used in Germany. The physharmonica resembles a small harmonium, but is differentiated from it by having no stops; being without percussion action, it does not speak readily or clearly. As a harmonium, the bellows are worked by the feet; by an alternate movement, which also affords a means of varying the dynamic force of the tone according as more or less energetic pedaling increases or decreases the pressure of the wind supply. The physharmonica was invented in 1818 by Anton Hâckel, of Vienna; in the original instrument the bellows were placed right and left immediately under the shallow wind-chest, and were worked by means of pedals connected by stout wire. A specimen, having a compass of four octaves and a very sweet tone, is preserved in the collection of Paul de Wit, formerly in Leipzig, now transferred to Cologne.

(K. S.)

PHYSICAL PHENOMENA, in the terminology of spiritualism and psychical research, mental or molecular phenomena in the physical world not traceable to ordinary causes and referred to the action of spirits or of mediums in abnormal psychical states. Among the phenomena or alleged phenomena are: materialization, levitation or elongation of the medium; passage of matter through matter, alteration of weight in a balance, tying of knots in an endless cord, apports (objects brought from a distance) and movements of objects (telekinesis); the production of writing, imprints of plaster or other objects; raps, voices and other sounds, including music; spirit photographs; lights and perfumes. To these may be added immunity against the effects of fire and the untangling of ropes.

Analogous phenomena are found in many parts of the world (see POLTERGEIST; FIREWALKING); spectral lights are associated with the tombs of Mahomedan saints, with Buddhist shrines, with religious revivals, with Red Indian and other magicians, &c., and as sporadic phenomena in the Highlands and Norway. Levitation is asserted of Australian wizards, the rope-trick of Eskimo angeloks; glyphs and direct writing are found in Mexican and Tibetan cults.

See F. Podmore, Modern Spiritualism; F. W. H. Myers, Human Personality, i. 506; Journal S. P. R., vii. 309 sq.

(N. W. T.)

PHYSIOCRATIC SCHOOL, the name given to a group of French economists and philosophers. The heads of the school were François Quesnay (q.v.) and Jean Claude Marie Vincent de Gournay. The principles of the school had been put forward in 1755 by R. Cantillon, a French merchant of Irish extraction (Essai sur la nature du commerce en général), whose biography W. S. Jevons has elucidated, and whom he regards as the true founder of political economy; but it was in the hands of Quesnay and Gournay that they acquired a systematic form, and became the creed of a united group of thinkers.
and practical men, bent on carrying them into action. The members of the group called themselves les économistes, but it is more convenient, because unambiguous, to designate them by the name physiocrates (Gr. οίκος, nature, and σπαρτεύς, to rule), invented by P. S. Dupont de Nemours (1739–1817), who was one of their number. In this name, intended to express the fundamental idea of the school, much more is implied than the subjection of the phenomena of the social, and in particular the economic, world to fixed relations of coexistence and succession. This is the positive doctrine which lies at the bottom of all true science. But the law of nature referred to in the title of the sect was something quite different. The theological dogma which represented all the movements of the universe as directed by divine wisdom and benevolence to the production of the greatest possible sum of happiness had been transformed in the hands of the metaphysicians into the conception of a jus naturae, a harmonious and beneficial code established by the favourable entity of these thinkers, nature, antecedent to human institutions, and furnishing the model to which they should be made to conform.

The general political doctrine is as follows: Society is composed of a number of individuals, all having the same natural rights. If all do not possess (as some members of the negative school maintained) equal capacities, each can at least best understand his own interest, and is led by nature to follow it. The social union is really a contract between these individuals, the object of which is the limitation of the natural freedom of each just so far as it is inconsistent with the rights of the others. Government, though necessary, is a necessary evil; and the governing power appointed by consent should be limited to the amount of interference absolutely required to secure the fulfilment of the contract. In the economic sphere this implies the right of the individual to such natural enjoyments as he can acquire by his labour. That labour, therefore, should be undisturbed and unfettered, and its fruits be guaranteed to the possessor; in other words, property should be sacred. Each citizen must be allowed to make the most of his labour; and therefore freedom of exchange should be ensured, and competition in the market should be unrestricted, no monopolies or privileges being permitted to exist.

The physiocrats then proceed with the economic analysis as follows: Only those labours are truly “productive” which add to the quantity of raw materials available for the purposes of man; and the real annual addition to the wealth of the community consists of the excess of the mass of agricultural products (including, of course, metals) over their cost of production. On the amount of this produit net depends the well-being of the community and the possibility of its advance in civilization. The manufacturer merely gives a new form to the materials extracted from the earth; the higher value of the object, after it has passed through his hands, only represents the quantity of provisions and other materials used and consumed in its elaboration. Commerce does nothing more than transfer the wealth already existing from one hand to another; what the trading classes gain thereby is acquired at the cost of the nation, and it is desirable that its amount should be as small as possible. The occupations of the manufacturer and merchant, as well as the liberal professions, and every vocation save the “unproductive” indeed, but they are “sterile,” drawing their income, not from any fund which they themselves create, but from the superfluous earnings of the agriculturist. The revenue of the state, which must be derived altogether from this net product, ought to be raised in the most direct and simplest way—namely, by a single impost of the nature of a land tax.

The special doctrine relating to the exclusive productiveness of agriculture arose out of a confusion between “value” on the one hand and “matter and energy” on the other. A. Smith and others have shown that the attempt to fix the character of “sterility” on manufactures and commerce was founded in error. And the proposal of a single impôt territorial falls to the ground with the doctrine on which it was based. But such influence as the school exerted depended little; if at all, on these peculiar tenets, which indeed some of its members did not hold. The effective result of its teaching was mainly destructive. It continued in a more systematic form the efforts in favour of the freedom of industry already begun in England and France. It was to be expected that the reformers should, in the spirit of the negative philosophy, exaggerate the vices of established systems; and there can be no doubt that they condemned too absolutely the economic action of the state, both in principle and in its historic manifestations, and pushed the laissez-faire doctrine beyond its just limits. But this was a necessary incident of their connexion with the revolutionary movement, of which they really formed one wing. In the course of that movement, the primitive social contract, the sovereignty of the people and other dogmas now seen to be untenable, were habitually invoked in the region of politics proper, and had a transitory utility as ready and effective instruments of warfare. And so also in the economic sphere the doctrines of natural rights of buying and selling, of the sufficiency of enlightened selfishness as a guide in mutual dealings, of the certainty that each member of the society will understand and follow his true interests, and of the coincidence of those interests with the public welfare, though the principles were of no practical examination, were of the overthrow of the established order.

These conclusions as to the revolutionary tendencies of the school are not at all affected by the fact that the form of government preferred by Quesnay and some of his chief followers was what they called a legal despotism, which should embrace within itself both the legislative and the executive function. The reason for this preference was that an enlightened central power could more promptly and efficaciously introduce the policy they advocated than an assembly representing divergent opinions and fettered by constitutional checks and limitations. Turgot used the absolute power of the Crown to carry into effect some of his measures for the liberation of industry, though he ultimately failed because unsustained by the requisite force of character in Louis XVI. But what the physiocratic idea with respect to the normal method of government was appears from Quesnay's advice to the dauphin, that when he became king he should “do nothing, but let the laws rule,” the laws having been, of course, first brought into conformity with the jus naturae. The partiality of the school for agriculture was in harmony with the sentiment in favour of “nature” and primitive simplicity which then showed itself in so many forms in France, especially in combination with the revolutionary spirit, and of which Rousseau was the most conspicuous exponent. Many members of the physiocratic group were undoubtedly men of thorough uprightness, and inspired with a sincere desire for the public good, especially for the material and moral elevation of the working classes. Quesnay was physician to Louis XV., and resided in the palace at Versailles; but in the midst of that corrupt court he maintained his integrity, and spoke with manly frankness what he believed to be the truth. And never did any statesman devote himself with greater singleness of purpose or more earnest endeavour to the service of his country than Turgot, who was the principal practical representative of the school.

Thus the physiocratic school never obtained much direct popular influence, even in its native country, though it strongly attracted many of the more gifted and earnest minds. Its members, writing on dry subjects in an austere and often heavy style, did not find acceptance with a public which demanded before all things charm of manner in those who addressed it. The physiocratic tenets, which were in fact partly erroneous, were regarded by many as chimerical, and were ridiculed in the contemporary literature; as, for example, the impôt unique by Voltaire in his L'Homme aux quarante écus, which was directed in particular against P. P. Mercier-Lariviére (1720–1794). It was justly objected to the group that they were too absolute in their view of things; they supposed, as Smith remarks in speaking of Quesnay, that the body politic could thrive only under one precise régime—that, namely, which they recommended—and
PHYSIOGNOMY

thought their doctrines universally and immediately applicable in practice. They did not, as theorists, sufficiently take into account national diversities or different stages in social developments, nor did they, as politicians, adequately estimate the impediments which ignorance, prejudice and interested opposition present to enlightened statesmanship.

The physiocratic system, after guiding in some degree the policy of the Constituent Assembly, and awakening a few echoes here and there in foreign countries, soon ceased to exist as a living power; but the good elements it comprised were not lost to mankind, being incorporated into the more complete construction of Adam Smith.

See the article on QUESNAY, with bibliography appended thereto, also the articles on MARBAUX and TURGOT. Most French histories contain an account of the school; see especially Tocequeville, L’Ancien régime et la révolution, ch. iii.; Taine, Les Origines de la France contemporaine, vol. i.; R. Steurn, Les Finances de l’Ancien régime et de la révolution (1885); Droz, Histoire du régime de Louis XVI.; also L. de Lavergne, Économistes français du XVIIIe siècle; H. Higgs, The Physiocrats (London, 1897, with authorities).

PHYSIOGNOMY, the English form of the middle Greek φυσιογνωμία, a contraction of the classical φύσις γνώμη (from φύσις, nature, and γνώμη, an interpreter), (1) a term which denotes a supposed science and openly whipped until his body be lined with the dispositions marked by the lineaments of the body" (Racon); (2) is also used colloquially as a synonym for the face or outward appearance, being variously spelled by the old writers: fysenamy by Lydgate, phisomy in Udal's translation of Erasmus on Mark iv., physiomy in Bale's English Velaries (i. 2, p. 44), and fominie in All's well that ends well, iv. 5 (first folio).

Physiognomy was regarded by those who cultivated it as a twofold science: (1) a mode of discriminating character by the outward appearance, and (2) a method of divination from form and feature. On account of the abuses of the latter aspect of the subject its practice was forbidden by the English law. By the act of parliament of George II. c. 5 (1743) all persons pretending to have skill in physiognomy were deemed rogues and vagabonds, and were liable to be publicly whipped, or sent to the house of correction until next sessions.1 The pursuit thus stigmatized as unlawful is one of great antiquity, and one which in ancient and medieval times had an extensive though now almost forgotten literature. It was very early noticed that the good and evil passions by their continual exercise stamp their impress on the face, and that each particular passion has its own expression. Thus far physiognomy is a branch of physiology. But in its second aspect it touched divination and astrology, of which Galen2 says that the physiognomical part is the greater, and this aspect of the subject bulked largely in the fanciful literature of the middle ages. There is evidence in the earliest classical literature that physiognomy formed part of the most ancient practical philosophy. Homer was a close observer of expression and of appearance as correlated with character, as is shown by his description of Thersites3 and elsewhere. Hippocrates, writing about 450 B.C., expresses his belief in the influence of environment in determining disposition, and in the reaction of these upon feature,4 a view in which he is supported later by Trogus. Galen, in his work Περὶ τῶν γυνῶν ἐθνῶν, has discussed the nature and immortality of the soul, proceeds in ch. vii. to a brief study of physiognomy (ed. Kühn iv. 795). In the animal he separated certain bodily physiognomical characteristics, saying that he might criticize them but feared to waste time and become tedious over them. In chapter viii. he quotes with approbation the Hippocratic doctrine referred to above; and 1 The Act 39 Elizabeth c. 4 (1597-1598) declared "all persons faying to have knowledge of Phisiognomie or like Fantastical Ymaginacious" liable to "be stripped naked from the middle upwards, and all his fingers dipped in blood." This was modified by 13 Anne c. 26 (1725), still further by 17 George I. c. 5, which was re-enacted by the Vagrancy Act 1824. This last act only specifies palmyria.

2 Galen, Περὶ καταλλήλων προκρισίας (ed. Kühn xix. 530).

3 Ibid., ii. 214. See also Blackwell’s Inquiry, (2nd ed. 1736), p. 330.

A physiological study of the Homeric heroes is given by Malahas, Chronogy, ed. Dindorf, v. 105.

4 Περὶ ἄνω τῆς, ἑλλόν, ὑπόν (ed. Kühn, i. 547).

In a later work, Περὶ καταλλήλων προκρισίας, he speaks of the advantage of a knowledge of physiognomy to the physician.4 We learn both from Iamblichus5 and Porphyry6 that Pythagoras practised the diagnosis of the characters of candidates for pupillage before admitting them, although he seems to have discredited the current physiognomy of the schools, as he rejected Cylo, the Crotonian, on account of his professing these doctrines, and thereby was brought into some trouble.7 Plato also tells us that Socrates predicted the promotion of Alcibiades from his appearance; and Apuleius8 speaks of Socrates recognizing the abilities of Plato at first view. On the other hand, it was observed by Cicero9 that a certain physiognomist, Zopyrus, who professed to know the habits and manners of men from their bodies, eyes, face and forehead, characterized Socrates as stupid, sensual and dull (bursus), "in quo Alcibiades cahinnum dicitur sustulisse." Alexander Aphrodisiensis adds that, when his disciples laughed at the judgment, Socrates said it was true, for such had been his nature before the study of philosophy had modified it. Zopyrus is also referred to by Maximus Tyrius10 as making his recognitions "intuiit solo."

That one's occupation stamps its impress on the outward appearance was also noticed at an early period. In the curious jargon in the Syllogismi in Quodlibet of 1580 B.C., Duan, son of Khru, expatiates on the effects of divers handcrafts on the workmen as compared with the elevating influences of a literary life.11 Josephus tells us that Caesar detected the pretence of the spurious Alexander by his rough hands and surface.12 The first systematic treatise which has come down to us is that attributed to Aristotle,13 in which he devotes six chapters to the consideration of the method of study, the general signs of character, the particular appearances characteristic of the dispositions, of strength and weakness, of genius and stupidity, of timidity, impudence, anger, and their opposites, &c. Then he studies the physiognomy of the sexes, and the characters derived from the different features, and from colour, hair, body, limbs, guilt and voice. He compares on charitres of mankind to animals, the male to the lion, the female to the leopard. The general character of the work may be gathered from the following specimen. While discussing noses, he says that those with thick bulbous ends belong to persons who are insensitive, swinish; sharp-tipped belong to the irascible, those easily provoked, like dogs; rounded, large, obtuse noses to the magnanimous, the lion-like; slender hooked noses to the eagle-like, the noble but grasping; round-tipped retroussé noses to the luxurious, like barndoor fowl; noses with a very slight notch at the root belong to the impudent, the crow-like; while snub noses belong to persons of luxurious habits, whom he compares to the horse.14

The practice of physiognomy is alluded to in many of the Greek classics.15 Apion speaks of the metoposcopists, who judge by the appearance of the face, and Cleanthes the Stoic says it is 1 Οπ. ιτι, xix. 330.

9 Ant., xvii. 12, 2.

10 Authors differ in their views as to its authenticity, but Diogenes Laertius (v. 22) and Stobaeus (Ser. clxxxv.) both believe it to be genuine. The chief difficulty is the reference to a certain Sophist, Dionysius, but this is probably an interpolation. There are physiognomical writings in other writings of Aristotle (cf. Anal. pri., ii. c. 30; Hist. anim., i. 8, Sanch.) sufficient to justify the attribution to him. On this, see Franz, Preface, p. vi, seq., of his Scriptores physiognomiae veteres (Leipzig, 1786).

11 See an interesting paper on "Straining and Yawning as Signs of Madness" by Prinsep, Trans. Camb. Phil. Soc., i. 201), which refers to Aristoph. Wasps, 642, with which he compares Plautus, Menæchmi, 279. Other references exist to physiognomy in Celsidion, Isidorus, Melcetius and Nemesius, but none of any great importance.
possible to tell habits from the aspect (cf. Ecclus. xix. 29, 30). Polemon (c. a.d. 150) compiled a treatise (published 1534, in Latin) on the subject, similar in character to that of Aristotle, but he excels in graphic descriptions of different dispositions, and differs only from Aristotle in some of his animal comparisons. A more important work was written by a converted Jew, Adamantius, about a.d. 415. This is in two books, the first on the expression of the eye, the second on physiognomy in general, mostly Aristotelian in character.

Among the Latin classical authors Juvenal, Suetonius and Pliny in well-known passages refer to the practice of physiognomy, and numerous allusions occur in the works of the Christian Fathers, especially Clement of Alexandria and Origen (for example, the familiar passage in his work against Celsus, i. 33).1

While the earlier classical physiognomy was chiefly descriptive, the later medieval authors particularly developed the predictive and astrological side, their treatises often digressing into chiro- mancy, onychomancy, clidomancy, podoscopy, spasmatomancy, and other branches of prophetic folk-lore and magic.

Along with the medical science of the period the Arabs contributed to the literature of physiognomy; 'Ali b. Ragel wrote a book on naevi; Rhazes (940) devoted several chapters to it; and Averroes (1153) made many references to it in his De sanitate, p. 82 (Leiden, 1537). Avicenna also makes some acute physiognomical remarks in his De anima, which was translated by Michael Scot about 1270. Among medieval writers Albertus Magnus (born 1205) devotes much of the second section of his De animalibus to physiognomy; but this chiefly consists of extracts from Aristotle, Polemon and Loxus. He does not enter into the animal comparisons of his predecessors, but occupies himself chiefly with simple descriptive physiognomy as indicative of character; and the same is true of the scattered references in the writings of Duns Scotus and Thomas Aquinas. The famous sage of Bologna, Michael Scot, while court astrologer to the emperor Frederick II., wrote his treatise De hominis phisognomia, much of which is physiological and of curious interest. It was probably composed about 1272, but not printed until 1477. This was the first printed work on the subject. Physiognomy also forms the third part of his work De secretis naturae. In 1335 Pietro d'Abano delivered in Paris a course of lectures on this subject (afterwards edited by Blondus, 1544), a few years before he was burned for heresy.

The 16th century was rich in publications on physiognomy. The works of the classical authors before mentioned were printed, and other treatises were published by John de Indagine, Cocles, Andreas Corvus, Michael Blondus, Janus Curnaro, Anselm Douciel, Pomponius Ronsscus, Gratardus, Lucas Gauricus, Tricassus, Cardanus, Taisnierus, Magnus Hund, Rothman, Johannes Padovanus, and, greatest of all, Giambattista della Porta. The earliest English works were anonymous: On the Art of Foretelling Future Events by Inspection of the Hand (1594), and A Pleasant Introduction to the Art of Chirognomie and Physiognomy (1588). Dr Thomas Hill's work, The Contemplation of Mankynede, containing a singular Discourse after the Art of Phisignomie, published in 1571, is a quaintly written adaptation from the Italian authors of the day. The undated book on moles and naevi by "Merlin Britannicus," after the model of 'Ali ibn Ragel, is of about the same date.

The development of a more accurate anatomy in the 17th century has somewhat diminished the interest in physiognomy, by substituting fact for fiction; and consequently the literature, though as great in quantity, became less valuable in quality. The principal writers of this age were T. Campanella, R. Coclen- ius, Clement, Timpler, J. E. Gallmard, Moldenarius, Septfalias, Saunders, C. Lebrun (a precursor of Charles Bell), Elsboz, de la Bellière, J. Evelyn (in the appendix to Numismata), Baldus, Bulver (in his Pathomatomyom), Fuchs, Spontoni, Ghiradelli, Chiaramonti, A. Ingegneri, Finella, De la Chambre, Zanardus, R. Fludd, and others of less importance.

The 18th century shows a still greater decline of interest in physiognomy. Historians of philosophy, like J. Meursius and Franz, re-edited some of the classical works, and G. G. Fülborn reviewed the relation of physiognomy to philosophy. Indeed, the only name worthy of note is that of J. K. Lavater (q.v.).

The other authors of this century are Peuschel, Spon, Schutz, Wegelin, J. Pernet, Gittanner, Grohmann, and several anonymous writers, and from the anatomical side G. M. Lancisi, J. Parsons and Peter Camper. The popular style, good illustrations and pious spirit pervading the writings of Lavater have given to them a popularity they little deserved, as there is no system in his work, which chiefly consists of rhetorical comments upon the several portraits. Having a happy knack of estimating character, especially when acquainted with the histories of the persons in question, the good pastor contrived to write a graphic and readable book, but one much inferior to Porta's or Aristotle's as a systematic treatise. The treatises of Nicolai and of Lichtenberg were written to refute his theory. With Lavater the descriptive school of physiognomists may be said to have ended, as the astrological physiognomy expired with de la Bellière. The few works which have since appeared, before the rise of the physiological school of Sir Charles Bell and Charles Darwin, are undeserving of notice, the development of phrenology by having spread to some extent in the works of Thomas Sudermann, by taking it into whatever was likely to live of the older science. The writers of the 19th century are Hörstig, Maas, Rainer, Thoné, A. Störh, Schier, Dr Rubels, Polli, Cardona, Mastrian, Diez, Carus, Piderit, Burgess and P. Gratiolet.

The physiological school of physiognomy was foreshadowed by Parsons and founded by Sir Charles Bell, whose Essay on the Anatomy of the Expression, published in 1806, was the first scientific study of the physical manifestation of emotions in the terms of the muscles which produce these manifestations. In the later editions of this essay the thesis is elaborated with greater detail. Moreau's edition of Lavater, in 1807, was something along the same lines. In 1809 Dr George C. Calver showed his defence of a scientific physiognomy based on general physiological principles. The experiments of G. B. A. Duchenne (Mécanisme de la physiognomie humaine, Paris, 1862) showed that by the use of electricity the action of the separate muscles could be studied and by the aid of photography accurately represented. These observations confirmed by experimental demonstration the hypothetical conclusions of Bell. The machinery of expression having thus been indicated, the connexion of the physical actions and the psychic state was made the subject of speculation by Herbert Spencer (Psychology, 1855). These speculations were reduced to a system by Darwin (Expression of Emotions, 1872), who formulated and illustrated the bearing as fundamental physiological principles:—

(1) Certain complex acts are of direct or indirect service, under certain conditions of the mind, in order to relieve or gratify certain sensations or desires; and whenever the same states of mind are induced the same sets of actions tend to be performed, even when they have ceased to be of use. (2) When a directly opposite state of mind is induced the direct and opposite set of actions are produced, and there is a strong and involuntary tendency to perform a reverse action. (3) When the sensorium is strongly excited nerve-force is diminished in excess and is transmitted in the reverse directions, depending on the connexions of nerve-cells and on habit.

The last of these propositions is adversely criticized by P. Mantegazza as a truism, but it may be allowed to stand with the qualification that we are ignorant concerning the nature of the influence called "nerve-force." It follows from these propositions that the expression of emotion is, for the most part, not under control of the will, and that those striped muscles are the most expressive which are the least voluntary. To the foregoing may be added the following three additional propositions, so as to form a more complete expression of a physiological philosophy:—

(4) Certain muscles concerned in producing these skin-folds become strengthened by habitual action, and when the skin diminishes

---

1 For scriptural allusions to physiognomy see Vecchius, Observationes in ditt. script. (Naples, 1641). Other classical references are contained in the Prooemium to the 1593 edition of the works of Baptista Portae.
in elasticity and fairness with advancing age, the wrinkles at the right side of the face, as well as the contractions of the muscles fibres become permanent. (5) To some extent habitual muscular action of this kind may, by affecting local nutrition, alter the contour of such bones and cartilages as are related to the muscles of expression. (6) If the mental disposition and passions to which such actions are inherited by children from their parents, it may be that the facility in, and disposition towards, certain forms of expression are in like manner matters of heredity.

Illustrations of these theoretic propositions are to be found in the works of Bell, Duchenne and Darwin, and in the later publications of Theodor Fiterit, Minike and Physiognomik (1886) and Mantegazza, Physiognomy and Expression (1890), to which the student may be referred for further information.

For information on artistic anatomy as applied to physiognomy see the catalogue of sixty-two authors by Ludwig Chouland, Geschichte und Bibliographie der anatomischen Abbildung, loc. cit. (Leipzig, 1852), and the works of the authors enumerated above, especially those of Aristotle, Franz, Porta, Cardan, Corvus and Bulwer. For physiognomy of disease, besides the usual medical handbooks, see Cabuchet, Essai sur l'expression de la face dans les maladies (Paris, 1801); Mantegazza, Physiognomy and Expression (1893), and Poli, Saggio di fotognomica e fotop genomia (1837). For ethnological physiognomy, see among other authors Graetzel, and amongst modern writers cited in the various textbooks on anthropology, especially Schadow, Physiognomische antike und naturaleische (1785), and Anne Hume, Anthrop. Inst. (1838). The study of the physical characteristics of criminals is discussed at great length by Lombroso, L'Uomo delinquente (1897); Ferrer, L'Onicidio (1895); and Baer, Der Verbrecher, 2. Aufl. (1831). The study of the physical habits of the prisoners (1890); and Haeckel, Uomo, il (1901).

PHYSIOLOGUS, the title usually given to a collection of some fifty Christian allegories much read in the middle ages, and still existing in several forms and in about a dozen Eastern and Western languages. As nearly all its imagery is taken from the animal world, it is also known as the Bestiary. There can be hardly a doubt about the time and general circumstances of its origin. Christian teachers, especially those who had a leaning towards Gnostic speculations, took an interest in natural history, partly because it was full of passages in Scripture that they wanted to explain, and partly on account of the divine revelation in the book of nature, of which also it was man's sacred duty to take proper advantage. Both lines of study were readily combined by applying to the interpretation of descriptions of natural objects the allegorical method adopted for the interpretation of Biblical texts. Now the early Christian centuries were anything but a period of scientific research. Rhetorical accomplishments were considered to be the chief object of a liberal education, and to this end every kind of learning was made subservient. Instead of reading Aristotle and other naturalists, people went for information to composite books on the works of Aelian, or to scattered folk tale-tellers' tales and fragments of misapprehended science were set forth in an elegant style. Theological writers were not in the least prepared to question the worth of the marvellous descriptions of creatures that were current in the schools on the faith of authorities vaguely known as "the history of animals," "the naturalists," and "the naturalist in the singular number (φυσιολόγος)." So they took their notions of strange beasts and other marvels of the visible world on trust and did their best to make them available for religious instruction. In some measure we find this practice adopted by more than one of the Fathers, but it was the Alexandrian school, with its pronounced taste for symbolism, that made the most of it. Clement himself had declared that natural lore, as taught in the course of higher Christian education according to the canon of truth, ought to proceed from "cosmogony" to "the theological idea," and even in the little that is left of the works of Origen we have two instances of the proceeding in question. And yet the fact that these reappear in the Physiologus would not suffice to stamp the work as a series of extracts from Alexandrian writings, as parallels of the same kind can be adduced from Epiphanius (loc. cit.) and Eusebius of Ceasarea (Orph. Syr. ii. 17, 130). Father Cahier would even trace the book to Tatian, and it is true that that heresiarch mentions a writing of his own upon animals. Still, the context in which the quotation occurs makes it evident that the subject-matter was not the nature of particular species nor the spiritual lessons to be drawn therefrom, but rather the place occupied by animal beings in the system of creation. On the other hand, the opinion of Cardinal Pitra, who referred the Physiologus to the more orthodox though somewhat peculiar teaching of the Alexandrians, is fully borne out by a close examination of the irregularities of doctrine pointed out in the Physiologus by Cahier, all of which are to be noted with in Origen. The technical words by which the process of allegorizing is designated in the Physiologus, like ἀρκεφάλης, θεωρία, ἀναγνώσεις, ἄλλογγραφα, are familiar to the students of Alexandrian exegesis. It has, moreover, been remarked that almost all the animals mentioned were at home in the Egypt of those days, or at least, like the elephant, were to be seen there occasionally, whereas the structure of the hedgehog, for instance, is explained by a reference to the sea-porcupine, better known to fish-buyers in the Mediterranean. The fables of the phoenix and of the conduct of the wild ass and the ape at the time of the equinox owe their origin to astronomical symbols belonging to the Nile country. In both chapters an Egyptian name is named, and elsewhwere the antelope bears its Coptic name of "anthelopes." That the substance of the Physiologus was borrowed from commentaries on Scripture and is confirmed by many of the sections opening with a text, followed up by some such formula as "but the Physiologus says." When zoological records failed, Egypto-Hellenic ingenuity was never at a loss for a fanciful invention distilled from the text itself, but which to succeeding copyists appeared as part of the teaching of the original Physiologus. As a typical instance we may take the chapter on the ant-lion—not the insect, but an imaginary creature suggested by Job, iv. 11. The original Hebrew for a lion (lyyin) appeared to the Septuagint translators to call for a special rendering, and as there was said to exist on the Arabian coast a lion-like animal called "myrmex" (see Strabo xvi. 774; Aelian, N.A., vii. 47) they ventured to give the compound noun "myrmekoleon." After so many years the commentators had lost the key to this unusual term, and only knew that in common Greek "myrmex" meant an ant. So the text "the myrmekoleon hath perished for that he had no nourishment" set them pondering, and others reproduced their meditations, with the following result: "The Physiologus relates about the ant-lion: his father hath the shape of a lion, his mother that of an ant; the father liveth upon flesh, and the mother her life upon honey. This is the ant-lion, a compound of both, and in part like to either, for his fore part is that of a lion, and his hind part like that of an ant. Being thus composed, he is neither able to eat flesh like his father, nor herbs like his mother; therefore he perisheth from inanimation"; the moral follows.

At a later period, when the Church had learnt to look with suspicion upon devotional books likely to provoke the scoffing of some and lead others into heresy, a work of this kind could hardly meet with her approval. A synod of Pope Gelasius, held in 496, passed censure, among others, on the "Liber Physiologus, qui ab haereticis consecratus est et B. Ambrosii nomine signatus, apocryphus," and evidence has even been offered that a similar sentence was pronounced a century before. Still, in spite of such measures, the Physiologus, like the Church History of Eusebius or the Pastor of Hermas, continued to be read with general interest, and even Gregory the Great did not disdain to allude to it on occasion. Yet the Oriental versions, which had certainly nothing to do with the Church of Rome, show that there was no systematic revision made according to the Catholic
PHYSIOLOGUS

standard of doctrine. The book remained essentially the same, albeit great liberties were taken with its details and outward form. There must have been many imperfect copies in circulation, from which people transcribed such sections as they found or chose, and afterwards completed their MS, as occasion served. Some even rearranged the contents according to the alphabet or to zoological affinity. So little was the collection considered as a literary work with a definite text that every one assumed a right to abridge or enlarge, to insert ideas of his own, or fresh scriptural quotations; nor were the scribes and translators by any means scrupulous about the names of natural objects, and even the passages from Holy Writ. Physiologus had been abandoned by scholars, and left to take its chance among the tales and traditions of the uneducated mass. Nevertheless, or rather for this very reason, its symbols found their way into the rising literature of the vulgar tongues, and helped to quicken the fancy of the artists employed upon church buildings and furniture.

The history of the Physiologus has become entwined from the beginning with that of the commentaries on the account of creation in Genesis. The principal production of this kind in our possession is the Hexameron of Basil, which contains several passages very like those of the Physiologus. For instance, in the seventh homily the fable of the nuptials of the viper and the conger-eel, known already to Aelian and Oppian, and proceeding from a curious misreading of Aristotle (Hist. An. v. 4, § 40 b, Bekk.), serves to point more than one moral. Notwithstanding the difference in theology, passages of this kind could not but be welcome to the admirers of the Alexandrian allegories. In fact, a medley from both Basil and the Physiologus exists under the title of the Hexameron of Eustathius; some copies of the first bear as a title Προς φυσιολογος, and in a Milan MS. the "morals" of the Physiologus are ascribed to Basil. The Leyden Syrac is supplemented with literal extracts from the latter, and the whole is presented as his work. Other copies give the names of Gregory Theologus, Ephræms, Chrysostom and Isidore.

As far as can be judged, the emblems of the original Physiologus were the following: (1) the lion (footprints rubbed out with tall; sleeps with eyes open; cubs receive life only three days after birth by their father's breath); (2) the sun-lizard (restores its sight by looking at the sun); (3) the charadrius (Deut. xiv. 16: presages recovery or death of prey; (4) the conger-eel which has its own head and tale); (5) the owl (nyktikorax; loves darkness and solitude); (6) the eagle (renews its youth by sunlight and bathing in a fountain); (7) the phoenix (revives from fire); (8) the hoopoe (redeems its parents from the ill of old age); (9) the wild ass (suffers no male besides itself); (10) the viper (born at the cost of both its parents' death); (11) the serpent (sheds its skin; puts aside its venom before drinking; is afraid of man in a state of nudity; hides its head and abandons the rest of its body); (12) the ant (orderly and laborious; prevents stored grain from germinating; distinguishes wheat from barley on the stalk); (13) the sirens and onocentours (Isa. xlii. 21, 22; compound creatures); (14) the hedgehog (pricks grapes upon its quills); (15) the toad (catches fat; simulating death); (16) the panther (spotted skin; enmity to the dragon; sleeps for three days after meals; allures its prey by sweet odour); (17) the sea-tortoise (or aspidochelone; mistaken by sailors for an island); (18) the partridge (hatches eggs of other birds); (19) the vulture (assisted in birth by a stone with loose kernel); (20) the ant-lion (able neither to take the one food nor digest the other); (21) the wasel (conceals by the mouth and brings forth by the ear); (22) the unicorn (caught only by a virgin); (23) the beaver (gives up its testes when pursued); (24) the hyaena (a herbivoride); (25) the otter (enhydris; enters the crocodile's mouth to kill it); (26) the kine (covers itself with mud to kill the dragon; another version of No. 23); (27) the crow (takes but one consort in its life); (28) the turtle-dove (same nature as No. 27); (29) the frog (either living on land and killed by rain, or in the water without ever seeing the sun); (30) the stag (destroys its enemy the serpent); (31) the salamander (quenches fire); (32) the diamond (powerful against all danger); (33) the swallow (brings forth but once; misreading of Aristotle, Hist. An. v. 13); (34) the tree called peripixion (protects pignes from the serpent by its shadow); (35) the pigeons (of several colours; led by one of them, which is of a purple or golden colour); (36) the antelope (or hydrippus; caught by its horns in the thicket); (37) the fire- lizard (a two sexed species); (38) the shark; (39) the saw-fish (sails in company with ships); (40) the ibis (flies only along the shore); (41) the ibex (descreses a hunter from afar); (42) the diamond again (read "carbuncle"); found only by night; (43) the elephant (conceives after partaking of mandrake; brings forth in the water; the young produced by the serpent from the father; when fallen is lifted up only by a certain small individual of its own kind); (44) the agate (employed in pearl-fishing); (45) the wild ass and ape (mark the equinoxes); (46) the Indian stone (relieves patients of the dropsy); (47) the aeron (touches no dead body, and keeps to one dwelling-place); (48) the sycamore (or wild fig; grubs living inside the fruit as coming out); (49) the ostrich (devours all sorts of things; forgetful of its own eggs). Besides these, or part of them, certain copies contain sections of unknown origin about the bee, the stork, the tiger, the woodpecker, the spider and the wild boar.

The Greek text of the Physiologus exists only in late MSS., and has to be corrected from the translations in all known full copies of 6th-century MS., published in J. P. N. Land's Anecdota syriaca; thirty-two chapters with the "morals" left out in a very late Vatican copy, published by Tychsen; and about the same number in a later one in a British MS. In an Armenian MS. in the Bibliothèque Nationale, a few chapters of the Spicilegium solemnse, and another version of thirty-seven chapters at Leiden, probably the work of a monk at Jerusalem, which Land translated and printed with the Syriac. The Latin versions of which we know are, after the Greek, the Arabic (19), the Persian (21), and the Hindustani (45). The whole of this work was the last printed in 1616. The physiologum, as such, is no longer found in libraries, but it is far from improbable that some of the versions of the book either remain to be detected or are now lost past recovery. A full account of the history of the Physiologus should also embrace the subjects taken from the productions of Christian art, the parables suggested by the original work, e.g. the Bestiarii d'amours of Richard de Fournival, and finally the traces left by it upon the encyclopaedic and literary work of the later middle ages.

The fullest and most complete account obtainable is to be found in the following works and such as are there quoted: S. Epiphanios ad physiologum, ed. Ponce de Leon with woodcuts (Rome, 1587); another edition, with copper-plates (Antwerp, 1588); S. Isidore, Hexameron commentarius, ed. Leo Allatius (Lyons, 1629; cf. H. Jan van Herwerden, Exercit. Crit., pp. 180-182, Hague, 1862); Physiologus syrius, ed. O. G. Tychsen (Krostok, 1705); Classici autores, ed. Mai, vili. 585-596 (Rome, 1835); J. B. Th. Tychsen, Melanges d'archeologie, &c. ii. 85 seq. (Vienna, 1815); Alger, Mélanges d'archeologie, &c. ii. 85 seq. (Paris, 1815), iii. 203 seq. (1853), iv. 55 seq. (1865); Cahier, Nouveau melanges (1874), p. 106 seq.); J. T. Pits, Specimina antiquitatum, ed. Strasbourg (Leiden, 1685); J. F. Maetzner, Allgem. Sprachproben (Berlin, 1867), vol. i. pt. i. p. 55 seq.; J. Victor Carus, Gesch. der Zoologie (Munich, 1872), p. 109 seq.; J. P. N. Land, Anecdota syriaca (Leiden, 1865, iv. 31 seq.); and in Verzamelingen der kon. Acad. van Wetenschappen, 2nd series, vol. iv. (Amsterdam, 1874); Mombi and Hoenuel in their
PHYSIOLOGY
(from Gr. φύσις, nature, and νοησις, discourse), the science or theory of the properties, processes and functions of living organisms.

Although physiology is distinguished from anatomy as the study solely with the functions of an organism, rather than its structure. The two main branches of the science are: animal and plant (vegetable) physiology, and in animal physiology that of man stands out as primarily associated with the word.

Ever since men began to take a scientific interest in the problems of life two distinct rival explanatory principles of vital phenomena have claimed attention: a natural and a mystical principle. The first outcome of the scientific attempt to explain vital phenomena was the doctrine of the Pneuma, held by the followers of Hippocrates, which found its clearest expression in Galen's system. According to this doctrine, the origin of all vital phenomena was a very fine substance, the pneuma, which was supposed to exist in atmospheric air, to be inhaled into the lungs of man, and thus through the blood reach all the parts of the body, where it produced vital phenomena. This doctrine—an attempt to explain the phenomena of life which was not altogether natural, but even materialistic—was accepted by the middle ages together with Galen's system. With its translation into the Latin spiritus, however, the conception of the Pneuma lost its original force. The spiritus animalis of the middle ages developed into mystical powers; the result being the explanation of vital phenomena by a supernatural theory. Not until the scientific renaissance of the 16th and 17th centuries did views again undergo a change. After the establishment of a scientific method in physiology by William Harvey, and the development of Descartes' mechanical system of regarding living bodies, the natural explanation of vital phenomena once more universally found favour. Two schools arose, which endeavoured by dissimilar methods to find a mechanical explanation of vital phenomena: the iatrophysical, originating with the gifted and versatile Borelli, and the iatrochemical, founded by the Dutchman, F. de la Boë (Sylvius). But while both chemical and physical methods of explanation failed at such problems as, for instance, irritability and evolution, another change in opinion took place. By degrees there emerged once more the tendency to explain vital phenomena by mystical means, finding expression in the Animism of Stahl, to quote an example; and in the second half of the 18th century Vitalism, originating in France, began its victorious march throughout the whole scientific world.

Again the opinion came to be entertained that the cause of vital phenomena was a mystical power (force hyperméconique)—that "vital force" which, neither physical nor chemical in its nature, was held to be active in living organisms only. Vitalism continued to be the ruling idea in physiology until the middle of the 19th century, and its supremacy was only gradually overthrown by the great discoveries in natural science of that century. The chemical discoveries resulting from Wöhler's synthesis of urea first showed that typical products of the animal body, the production of which had hitherto been supposed to be solely the result of the operation of vital force, could be obtained artificially by purely chemical methods. Then above all came the discovery of the law of the Conservation of Energy by Robert Mayer (1814-1878) and Hermann von Helmholtz (1821-1894), and its application to the living organism by Mayer, Helmholtz, Pierre Louis Dulong (1785-1838), Edward Frankland, Max Rubner and others, to prove that the manifestations of energy by the organism are simply the result of the quantity of potential energy received into the body by means of food. Finally, the stupendous results arrived at by Darwin and the establishment of the fundamental law of "biogenesis" by Ernst Haeckel, prepared the way for a natural explanation of the enigma of evolution and structure of organisms. Thus by the second half of the 19th century the doctrine of vital force was definitely and finally overthrown to make way for the triumph of the natural method of explaining vital phenomena, which down to time has continued to spread and flourish with an unparalleled fertility. It would, it is true, appear as if in our day, after the lapse of half a century, mystical tendencies were again disposed to crop up in the investigation of life. Here and there is heard once more the watchword of Vitalism. But all the so-called neo-vitalistic efforts—such as those of Alexander von Bunge (1803-1890), Georg Egon Kindlisch (b. 1835), Johannes Reinke (b. 1849) and others—have nothing to do with the old Vitalism. They originate solely in a widespread confusion with regard to the boundaries of natural science, their principal tendency being to amalgamate psychological and speculative questions with problems of pure natural science. In the face of all these efforts, which by their unfortunate designations of Vitalism and Neo-vitalism give rise to entirely false conceptions, and which by their intermingling of psychological questions and questions of natural science have led to mere confusion in research, it is essential that natural philosophy should be called upon to realize its own limits, and above all clearly to understand that the sole concern of physical science is the investigation of the phenomena of the material world. Physiology, as the doctrine of life, must therefore confine itself to the material vital phenomena of organisms. It is self-evident, however, that only such laws as govern the material world will be found governing material vital phenomena—the laws, that is, which have hitherto been brought to their most exact and most logical development by physics and chemistry, or, more generally speaking, by mechanics. The explanatory principles of vital phenomena must therefore be identical with those of inorganic nature—that is, with the principles of mechanics.

The investigation of vital phenomena in this sense requires, in the first place, an exact knowledge of the substratum in which these phenomena are manifested, just as in chemistry and physics a thorough knowledge of the composition and functions of the material world is a necessary premise to the investigation of the phenomena of inorganic nature. The knowledge of the composition and structure of organisms has in the course of the scientific development of anatomy attained to an ever-increasing minuteness of detail, without having as yet reached a definite limit. The last important step in this direction was the discovery by Matthias Jakob Schleiden (1824-1881) and Theodor Schwann (1810-1882) that all organisms are built up of elementary living structural components, namely of cells (see CYTOLoGY). The details of the anatomical construction of organisms are described under various appropriate headings, and a general guide to these will be found under ANATOMY and ZOOLOGY. We would here merely point out that a cell is the simplest particle of living substance which appears to be permanently capable of life. Different elements are essential, however, to the existence of the cell—two, at least, so far as has hitherto been discovered—the protoplasm and the nucleus, and must at present be regarded as at least very doubtful whether the centroecome, which in recent times it has been possible to demonstrate as existing in very many cells, and which appears sometimes in the protoplasm, sometimes in the nucleus, is a general and third independent cell-constituent.

On the other hand, the number of special constituent parts which appear in various cell-forms is very large. A question which has long been discussed, and which has received special and animated attention, is that with regard to the finer structure of the cells—with regard, that is, to the protoplasm and the nucleus lying in it. Views on this subject have diverged very widely, and several totally diverse theories have been opposed to one another. One theory maintains that the living cell-substance has a reticular structure; another, that it is fibrilliferous. According to a third theory, the essence of the construction of the cell-substance lies in the granules which it contains; and according to a fourth, it lies in the ground-substance in which these granules are embedded. One view holds this ground substance to be homogeneous, another regards it as possessing a fine foam-structure. It may at present be regarded as...
incontrovertible that living substance is more or less fluid, and that there does not exist any general structure for all cell-forms. But in some special cases all the theories which have been quoted are to a certain extent correct. Different cells there are reticular, fibrous and granular differentiations respectively, and differentiations in foam-structure; in many cells, however, the protoplasm appears to be beyond doubt homogeneous and without a distinct structure, and only under certain conditions to assume changing structures. But the fact which is of most importance for the right understanding of vital phenomena is that the cell-substance is always more or less fluid, for only in a fluid substratum can such intense chemical processes be enacted as are to be found in every living cell.

Where the analytical powers of the microscope in anatomy can go no farther, chemical analysis of the composition of the cell steps in. By its means the discovery is made that there is no elementary difference between organic and inorganic nature, for only such chemical elements as are known to exist in the inorganic world are found in the organic. On the other hand, however, the living cell-substance possesses chemical compounds which find analogues nowhere in inorganic nature. The characteristic organic substances which are present in every cell are proteins and protein-compounds. Besides these there occur, widely disseminated, carbohydrates, fats and other organic substances, which partly originate in the decomposition of proteins and their compounds, and are partly used for their construction. Lastly, there are in addition great quantities of water and some inorganic salts.

Such are the structure and composition of the substratum in which vital phenomena play their part. When we consider vital phenomena themselves in the various living organisms—in protista, plants, animals, man—there appears an incalculable diversity of phenomena. Here, however, as in the case of the structure of organisms, we have to analyse and to penetrate ever farther and deeper till we reach the fundamental phenomena. We then find that the great variety of vital manifestations may be traced back to a few fundamental general groups, which are precisely the same groups of phenomena as those to be observed in inorganic nature. All the processes that take place in the organic world may be regarded from the three different standpoints of their changes in substance, in energy and in form; for substance, energy and form are all necessary to our conception of matter. Accordingly, the general elementary vital phenomena likewise fall into three groups—metabolism, the mechanism of energy, and the assumption of form. Every cell, so long as it is living, takes in certain substances from its environment, submits them to chemical transformation in its interior, and gives out other substances. This metabolism is manifested in several special functions—in nutrition and digestion, respiration and circulation, secretion and excretion. The essence of the whole process is the fact that while out of these ingested stuffs living substance is always again being formed by the living substance which already exists, it is itself continually undergoing decomposition, and the products of this decomposition are what the cell gives off again to the outside. With metabolism, however, there is inseparably associated a transformation of energy. These substances taken in by the cell contain a large quantity of potential energy, which is transformed into kinetic energy. This has for its result the manifold activities of the organism, more especially motion, heat, electricity and light. Finally, the chemical transformations in living substance may also manifest themselves outwardly in changes of form, e.g. the growth generally in the matter of growth, reproduction and development. The three general elementary groups of vital phenomena are therefore in reality merely the expression of the various aspects of one and the same process—of the actual vital process itself. The ultimate object of all physiology is to discover what this vital process is—that is to say, what is the exact cause of these manifold vital phenomena—a goal from which it is at the present day still very remote.

As every physical and chemical phenomenon of inorganic nature occurs only under distint conditions, so vital phenomena are also dependent upon certain conditions of life. Every living body, every living cell, requires food, water, oxygen, and, further, a certain temperature and a certain pressure in its environment. These are the general conditions of life. But the special conditions on which depends the continued existence of the individual forms of organisms are as numerous as the forms of organisms themselves. Now, just as the physicist or chemist varies those conditions under which a phenomenon occurs in order to get at its causes, so does the physiologist try to experiment with vital phenomena, altering the vital conditions: and testing the changes which are thereby produced. The great importance of this method consists in the power it gives the experimenter of analysing vital phenomena systematically from definite points of view. Every change in its normal vital conditions which produces any effect upon an organism is termed a stimulus. This is the only general definition we have for a conception which is of such vast importance to physiology. According to it, experimental physiology is entirely a physiology of stimuli. It further follows from this conception of stimulation that there must be an enormous multiplicity of stimuli, since each particular vital condition may be subjected to some change capable of acting upon it as a stimulus. But, besides this, other factors may be brought to bear upon organisms which have absolutely no place among their vital conditions; for instance, many chemical resgents and physical stimuli, which, although they are not the general definition of stimulus, because they likewise imply a change in the conditions under which the organism lives. From their qualitative nature stimuli are distinguished as chemical, thermal, photic, mechanical and electrical. Each of these several varieties may, however, be applied quantitatively in various degrees of intensity, and may in consequence produce quite different results. This opens up to experimental physiology a vast field of research. But the physiology of stimulation is not only of the greatest value as a means of research: its importance is much increased by the fact that in nature itself stimuli are everywhere and constantly acting upon the organism and its parts. Hence the investigation of their action comes to be not merely a means, but a direct end of research.

Although it is not at present possible to define all the laws that govern stimulation, on the one hand because the number of stimulating effects known to us in the whole organic world is as yet too limited, and on the other because those already known have not yet been thoroughly analysed, yet it is within our power to classify stimulating effects according to their various characteristics, and to ascertain a few facts concerning their general and fundamental conformity to law. The first fact, as appears from a glance at a great many of the various forms of stimulation, is that all their effects are manifested in either a quantitative or a qualitative alteration of the characteristic vital phenomena of each living object. The quantitative is the usual mode of action of stimuli. It is generally found that a stimulus either increases or diminishes the intensity of vital phenomena. In the first case the effect is one of excitation; in the second of depression. It is the more important to bear in mind this twofold operation of stimuli, owing to the fact that in former times physiologists were very apt to conceive of excitation and stimulation as identical. It is not, however, an undisputed fact that depression may also occur as a typical effect of stimulation. This is most apparent in cases where the same stimulus that produces excitation may on being applied for a longer period and with greater intensity, produce depression. Thus narcotics (alcohol, ether, chloroform, morphia, &c.) on certain forms of living substance produce the phenomena of excitation when their action is weak, whereas when it is stronger they produce complete depression. Thus, likewise, temperature stimuli act differently upon vital phenomena according to the degree of temperature: very low temperatures depressing,
PHYSIOLOGY

medium temperatures exciting with increasing intensity, and higher temperatures from a certain height upwards again depressing. The effects of stimulation are not, however, always manifested in merely quantitative changes of the normal vital phenomena. Sometimes, especially in the case of long uninterrupted and chronic stimuli, stimulation is found gradually to produce phenomena which are apparently quite foreign to the normal vital phenomena of the cell in question. Such qualitative alterations of normal vital phenomena are perceptible chiefly in chronic maladies in the cells of different organs (the heart, liver, kidneys, spleen, &c.), in which the vital conditions become gradually more and more modified by the cause of the malady.

To this category pertain all the so-called chronic processes of degeneration which in pathology are known as fatty degeneration, mucous degeneration, amyloid degeneration, and so forth. The characteristic element in all these processes is that the normal metabolism is disturbed into a strange channel by the altered vital conditions of the cells of the organ affected, so that substances are formed and accumulated in the cell which are entirely foreign to its normal life. But this class of stimulation is still very obscure as regards causes and inner processes, and it is within the range of possibility that the ultimate cause of the qualitative changes in the normal metabolism is to be found simply in the processes of excitation and depression which chronic stimulation produces in separate parts of the metabolism. Thus, at least with regard to fat-metamorphosis (fatty degeneration), it is highly probable that fat is deposited in the protoplasm simply because, owing to an inadequate supply of oxygen, it cannot, when it originates, be oxidized in the same proportion as it is formed, whereas in the normal cell all fat which originates in metabolism is consumed as soon as it is produced. According to this conception, therefore, fatty degeneration is attributable primarily to a depression of the processes of oxidation in the cell.

If we may accept this view as correct with regard to the other metamorphic processes also, the qualitative changes in vital phenomena under the influence of stimuli would after all depend simply upon the excitation or depression of the constituent parts of the vital process, and, according to such a view, all stimuli would act primarily only as exciting or as depressing agents upon the normal process of life.

In accordance with the three groups into which general vital phenomena are divided, it follows as a matter of course that the excitation or depression produced by a stimulus can manifest itself in the cell's metabolism, assumption of form, and manifestation of energy. The effects of excitation upon the production of energy are the most striking, and were therefore in former times frequently thought to have a claim par excellence to rank as stimulating effects. These reactions attract most attention in cases where the production of energy is proportionately very great—as with muscle, for instance, which is made to twitch and perform work by the process of discharge (Ausschüttungsvorgänge), however, lie at the bottom of cases like these. Potential chemical energy, which is stored up in a considerable quantity in living substance, is converted by the impulse of the stimulus into kinetic energy. Therefore the amount of the effect of stimulation—that is to say, the quantity of work performed—bears no proportion whatever to the amount of energy acting as a stimulus upon the muscle. The amount of energy thus acting may be very small as contrasted with an enormous production of energy on the part of the living substance. It will not do to make generalizations, however, with regard to this proportion, as was frequently done in former times. All processes of stimulation are not processes of discharge. The influence of many stimuli, as has been observed, is far more in depression than in excitation, so that in certain circumstances a stimulus actually diminishes the normal liberation of energy. There is therefore no general law as to the proportion which the amount of energy acting as a stimulus upon living substance bears to the amount of energy liberated.

Among special varieties of stimulation there is one class of stimuli which has attracted particular attention—namely, those which act unilaterally upon free-moving organisms. It is principally with the lowest forms of life that we have here to do—unicellular protista and free-living cells in the bodies of higher organisms (sperm-cells, leucocytes, &c.). When from some reason a stimulus—be it chemical, thermal, photic, electrical, or of any other kind—is applied to these organisms in their medium, they are impelled to move in a course bearing a definite relation to the source of the stimulus, either directly towards that source or directly away from it, more rarely in a course transverse to it. This directive action of stimulation is under such a fixed conformity to law, that it vividly recalls such purely physical processes as, for instance, the attraction and repulsion of iron particles by the poles of a magnet. For example, if light falls from one side upon a vessel full of water containing unicellular green algae, according to the intensity of the light these organisms swim either towards the illuminated side, where they form a compact mass on the edge of the vessel, or away from it, to cluster on the opposite edge. In the same way infusoria in water are observed to hasten towards or to flee from certain chemical substances, and leucocytes in our bodies act in the same manner towards the metabolic products of pus-forming bacteria which have penetrated into an open wound.

The suppuration of wounds is always accompanied by an amazing conglomeration of leucocytes at the seat of the lesion. Perhaps the most striking effects are those of the constant electric current upon unicellular organisms, since in this case the motion follows the cause with absolutely automatic regularity, certainty and rapidity. Thus, for example, after the establishment of the current many Infusoria (Paramecium) accumulate at the negative pole with great celerity and without deviation, and then are swept round again with equal celerity as soon as the direction of the current is altered. As such cases of directive stimulation may occur among all varieties of stimuli whenever stimuli act unilaterally, they have been designated, according to the direction in which they occur in relation to the source of the stimulus, as positive or negative chemotaxis, phototaxis, thermotaxis, galvanotaxis, and so forth. The strange and perplexing element in these phenomena becomes clear to us as soon as we know the characteristic method of locomotion for each form of organism, and whether the stimulus in question in the given intensity exercises an effect of excitation or of depression upon the special form. The direction of motion is then the essential mechanical result of unilateral stimulation of the organs of locomotion.

Seeing that these reactions are exceedingly widely distributed throughout the whole organic world, and possess a deep biological significance for the existence and continuance of life, the interest they have awakened is thoroughly justified.

One of the most important physiological discoveries of the 19th century was that of the "Specific Energy of Sense-substances." Johannes Müller was the first to establish the fact that very different varieties of stimuli applied to one and the same organ of sense always produce one and the same variety of sensation, and that, conversely, the same stimulus applied to the different organs of sense produces a different sensation in each organ—the one, in fact, which is its specific attribute. Thus, for example, mechanical, electrical and photic stimuli applied to the optic nerve produce no other sensation than that of light; and, conversely, any one variety of stimulus—take the electrical, for example—produces sensations of light, hearing, taste or smell, according as it affects the optic, auditory, gustatory or olfactory nerves. This law of the "Specific Energy of Sense-substances," as Johannes Müller (1809-1857) called it, has come to have a highly important bearing upon scientific criticism, since it proves experimentally that the sensations of the outer world are in themselves in no way discernible by us, but that—be it the same outward object—the electric current, or a mechanical pressure, for instance—we receive altogether different sensations and form altogether different conceptions according to the sense-organ affected. But this law does not possess significance for psychology alone; as regards physiology also it has a much more general and more comprehensive force than Müller ever anticipated. It holds good, as demonstrated by Ewald Hering (b. 1834) and others,
not of sense-substances only, but of living substance generally.
Each cell has its specific energy in Johannes Müller's sense, and
in its extended form there is no more general law for all the
operations of stimuli than this law of specific energy. To take
examples, whether a muscle be stimulated by a chemical,
mechanical, thermal or electrical stimulus the result is in each
case the same—namely, a twitching of the muscle. Let a salivary
gland be stimulated chemically, mechanically, electrically or
in any other way, there always follows the same specific action—
a secretion of saliva; no matter what be the kind of stimulus
acting upon it, the liver-cell always reacts by producing bile, and
so on. On the other hand, we have the same stimulus—the
electric current, for example—gives in each form of living
substance a specific result: twitching in the muscle, secretion
of saliva in the salivary gland, production of bile in the liver-cell,
&c.
That is, of course, with the proviso that the effect of the
stimulus be exciting and not depressing. The following general
formulation, however, of the law of specific energy brings the
depressing stimulus also within its scope: "Different stimuli
produce in each form of living substance an increase or a diminu-
tion of its specific activity." As already observed, it will
probably be found that those weak chronic forms of stimulation
which produce qualitative changes may also be comprised under
the general law.
The knowledge thus far acquired from analysis of vital
phenomena and their changes under the influence of stimuli
affords but a very indefinite temporary basis for
the theory of the actual vital process itself, of
which vital phenomena are the outward manifesta-
tion. The conceptions to which physiological research has
hitherto attained in this matter are of a more or less doubt-
ful nature. The facts contained in them still require to be
linked together by hypotheses if we are to obtain even a vague outline of what lies hidden behind the great riddle of life.
Such hypotheses, serving as they do to link facts consistently
together, are absolutely essential, however, to the further
progress of research, and without their aid any systematic
investigation would be impracticable. But at the same time it
must never be forgotten that these hypotheses are merely
provisional, and that whenever they are found to be no longer
in harmony with the widening range of new experiences and
ideas they must either be proved to be facts or be subjected to
modification. This is the point of view from which we must
deal with modern ideas concerning the nature of the actual vital
process—the mechanism of life.
The fundamental fact of life is the metabolism of living
substance which is continually and spontaneously undergoing
decomposition, and building up again, in the process and
with the help of the food-substances it takes in. These
processes of decomposition and of reconstruction may be
briefly designated as dissimilation (catabolism) and assimilation
(anabolism) respectively. Now the question arises: How are
we to understand this process of dissimilation and assimilation
from a mechanical standpoint? It is quite evident that we
have to do with some chemical occurrence; but how are the
chemical transformations brought about? There are obviously
two possibilities. It is conceivable that the decomposition of
food-stuffs and the formation of excretion-products in the cell-
body are caused by the repeated casual encounter of a great series
of chemical combinations and by their repeatedly reacting upon
one another in the same manner, bringing about transformations
and forming waste products which are excreted, while at the same
time certain chemical affinities are always taking in from without
new chemical combinations (food-stuffs) and uniting them.
This theory was in fact occasionally advanced in former times,
particularly in its chemical aspect, and the belief was especially
entertained that the enzymes in living substance might play an
important part in these transformations. This assumption,
however, leads to no clear and lucid image of what takes place,
and, moreover, draws too largely upon auxiliary hypotheses. It
has therefore met with but little acceptance. The other possible
explanation of metabolism is that its whole process is confined
to one single class of chemical combinations whose tendency it
is to be constantly undergoing spontaneous decomposition and
regeneration. This latter theory was founded by Ludimar
Herrmann (b. 1838), Eduard Friedrich Pflüger (b. 1829) and
others, and has met with universal recognition because of its
naturalness, simplicity and clearness.
Starting with this hypothesis, the path of further research
lies clear and well defined before us. In the first place, we are
obviously met by the question: What conception are
we to form of these combinations on which hinges the
whole vital process? Among the organic matters which compose
living substance, proteids perform the most important part.
In fact, all the proteid-compounds form the only organic matter
which is never absent from any cell. They form also the greater
part of all the organic compounds of the cell, unless reserve-stuffs
are accumulated to a considerable extent, and they are by far
the most complicated of the compounds of living substance.
While animal life is impossible without proteid food, there are,
on the other hand, animals which can continue to subsist on
proteid alone. This series of facts proves very conclusively
that proteids and their compounds play by far the most
important part of all organic matter in the processes of life. The
idea thus naturally presents itself that the required hypothetical
combination of forming and dissolving the proteid-matter will be
found to bear a very close relation to proteids. But another
point must be here considered. The proteids and their com-
 pounds known to us are, comparatively speaking, stable com-
 pounds, which never undergo spontaneous decomposition as
long as they are protected from outward injury, whereas the
hypothetical combination which lies at the centre of organic
metabolism is extraordinarily liable and continually undergoing
spontaneous decomposition. Therefore we have to think not
of ordinary proteids in this case, but of still more complicated
combinations, the atoms in the molecule of which have a strong
tendency to group themselves in new arrangements. Owing to
the rapidity of these arrangements these substances are termed "biogens." When we come to inquire how such labile
biogen molecules are built up out of the proteids of food, we
find our knowledge very much restricted. Doubtless the intra-
molecular addition of inspired oxygen has much to do with it;
for living substance when deprived of oxygen loses its irritability
—that is to say, its tendency to decomposition. The fact that the
decomposition of living substance is always associated with
the formation of carbonic acid—a circumstance obviously necessi-
ting the aid of oxygen—also points to the absolute indispens-
ableness of oxygen in the matter. Pflüger has further
suggested that the metabolism of living substance owes its liability
for the formation of carbonic acid when joined by oxygen
atoms principally to cyanogen groups which are contained in it.
According to this view, the following is supposed to be the process
of the formation of biogen molecules: It is assumed that the
biogen molecules already present in living substance take out
of the proteids of food certain groups of atoms, and dispose them
so as to produce cyanogen-like compounds. The addition of
oxygen atoms then brings the biogen molecule to the maximum
of its power of decomposition, so that—partly spontaneously,
but more especially when impelled by a stimulus—it breaks
down somewhat explosively, causing the formation of carbonic
acid. In this proceeding, according to the hypothesis which
is the most widely accepted and the most fruitful in results, would
lie the very germ of the vital process.
If we accept these views as far as their general principle is
concerned, assimilation is the re-formation of biogen molecules
by those already existing, aided by food-stuffs; dissimilation,
the decomposition of biogen molecules.
Mechanism of Cell-life.
To this primary process, however, is attached a whole
series of secondary chemical processes, which serve partly to
work upon the food so as to fit it for the building up of biogen
molecules, and partly to form out of the direct decomposition-products
of the biogen molecules the characteristic secretion-products
of living substance (excretions and secretions). The various
workings of matter in the cell are rendered very much more
complex by the circumstance that the living cell exhibits various morphological differentiations—above all, the differentiation in protoplasm and nucleos. Again, a transformation of energy is inseparably connected with metabolism. Along with food and oxygen potential chemical energy is continually being introduced into the cell, to be accumulated in the biogen molecules, and at their decomposition transformed into kinetic energy, which finds an outlet in the various manifestations of energy in the cell—motion, heat, and so forth. In the light of this hypothesis the operations of stimuli also become comprehensible. Seeing that there is an initial tendency to the occurrence of certain definite chemical processes, which are associated with the reconstruction and decomposition of biogen molecules, various stimuli will either further or hinder the course of these processes on a cell. One must therefore, to no outward disturbance, and which continues always in the unvarying medium provided by an exact sufficiency of food, will be in "metabolic equilibrium"—that is to say, its assimilation and its dissimilation will be equal (A = D). When, however, the influence of external stimuli is brought to bear upon them—that is to say, any change in their enveloping vital conditions—A and D will either be altered in similar proportion, or their mutual equilibrium will be disturbed. In the former case the vital processes will merely be intensified in their course; and in the latter case the result will be determined according to the part of metabolism thus excited or depressed. When the effect of a stimulus is to excite D continuously in a high degree without correspondingly increasing A, the result is a dying-off—an atrophy. In the contrary case, when A remains continuously greater than D, the result is growth, increase and reproduction of the cell. Experience proves, however, that A and D stand in a certain relation of mutual dependence to each other, with the result that when D has been increased by a stimulus, for example, A correspondingly increases during the stimulation, and continues to do so after its cessation, till the loss in living substance produced by the stimulation of D is eventually made good, and metabolic equilibrium is restored. When a muscle has been fatigued by some stimulation causing an enormous increase of D, there is a corresponding spontaneous increase in A. After some time the muscle is observed to have recovered. It has once more become capable of performing work; its metabolism is again in equilibrium.

The vital phenomena of the cell may be derived mechanically from metabolism and the changes it undergoes under the influence of stimuli. Our ability to do this will increase more rapidly or the better we come to understand the chemical processes of metabolism in the cell itself. The foregoing outline must be regarded, of course, as embodying only a fragmentary hypothesis, which can serve as a guide for further research only so long as it does not clash with facts, and which must be amplified, specialized and developed with the widening of specific knowledge regarding the cell's metabolism. The relations already known are so exceedingly complex that only by slow degrees can we pursue the investigation of separate fragments of the entire metabolic series. The differentiation of nucleus and protoplasm in the living substance of the cell alone gives rise to an extraordinary complication in the metabolic process, for these two parts of the cell stand in the most complicated correlation with one another as well as with the enveloping medium—a fact of which the experiments made by vivisection in various free-living cell-forms have furnished abundant evidence. The farther such knowledge advances, the more rounded, clear and free from hypotheses will become our conception of the cell's metabolism. But the cell is the elementary component part of all organisms, and from the life of individual cells is constructed the life of the separate tissues and various organs, and thus of the entire organism. Hence the cell is the only vital element which the organism possesses, and therefore the investigation of the vital processes in its separate cells leads ultimately to a knowledge regarding the mechanism of life in the whole.

Vegetable physiology is dealt with in the article PLANTS: Physiology. For details of different parts of the animal body, see ANIMAL HEAT; RESPIRATORY SYSTEM; VASCULAR SYSTEM; TOUCH; SMELL; SIGHT; HEARING; VOICE; MUSCLE AND NERVES; SLEEP; HYPNOTISM; BRAIN; SPINAL CORD; SYMPATHETIC SYSTEM; BLOOD; LYMPH; PHAGOCYTOSIS; DIGESTIVE ORGANS; NUTRITION, &c.

The principal modern English textbooks of animal physiology are Sir Michael Foster's (1909), Morley's (1906), Paton (1908), Halliburton (1909), and Starling (1909). See, however, the bibliographical notes to the separate articles.

(M. V.)

PIACENZA (Lat. Piacentia), a town and episcopal see of Emilia, Italy, the capital of the province of Piacenza, 42 1/4 m. S.E. of Milan and 91 m. N.W. of Bologna by rail. Pop. (1906), 55,786. It is bounded on the N. by the river Pavia, on the E. by the paralleling railway, on the S. by the provincial highway, and on the W. by the river Trebbia. It has a fine cathedral, a large university, and Roman antiquities. The cathedral was erected between 1122 and 1233, in the Lombard Romanesque style, under the direction of Santo da Sambuceto, on the site of a church of the 9th century which had been destroyed by earthquake. The west front has three doors with curious pilastered porches. The campanile is a massive square brick tower 223 ft. high; the iron cage attached to one of its windows was put up in 1495 by Ludovico il Moro for the confinement of the Duke of Savoy, afterwards of France. The crypt is a large church supported by one hundred pillars. This large edifice has been restored since 1868, and the frescoes by Guercino and Caracci, which decorate parts of its roof, though good in themselves, are inappropriate to its severe style. Sant' Antonino, which was the cathedral church till 877, is supposed to have been founded by St Victor, the first bishop of Piacenza, in the 4th century, and restored in 503; it was rebuilt in 1104, and altered in 1587. It was within its walls that the deputies of the Lombard League swore to the conditions of peace ratified in 1183 at Constance. The Gothic brick vestibule (Il Paradiso) on the north side is one of the older parts of the building. San Francesco, a spacious Gothic edifice begun by the Franciscans in 1278, was erected on the site of the palace of Ubertino Landi, a leader of the Ghibelline party. S. Savino, a fine Romanesque building of A.D. 903 (well restored in 1909), contains a mosaic pavement of this period with curious representations, including one of a game of chess. S. Sisto, which dates from 1490, and takes the place of the church founded in 874 by Angilberga (consort of the emperor Louis II.), lost its chief attraction when Raphael's Sistine Madonna (now in Dresden) was sold by the monks in 1754 to Frederick Augustus III. Its place, however, is occupied by a copy by Avanzini, and there are also several good altars by Bassetti, S. Sepolcro and S. Maria della Campagna are both good early 13th-century works. The latter is rich in frescoes by Pordenone. S. Anna, dating from 1334, was the church of the barefooted Carmelites. Of the secular buildings the most interesting is the Palazzo Communale, begun in 1281, one of the finest buildings of its kind in Italy. The square in front is known as the Piazza dei Cavalli, from the two bronze equestrian statues of Ranuccio (1620) and his father Alexander, prince of Parma, governor of the Netherlands (1623). Both were designed by Francesco Mocchi. The Palazzo dei Tribunali and the Palazzo degli Scoti are fine early Renaissance brick buildings with terra-cotta decorations. The huge Farnese palace was begun by Vignola's designs by Margaret of Austria in 1558, but it was never completed, and since 1800 it has been used as barracks. Other buildings or institutions of note are the old and the new bishop's palace, the fine theatre designed by Lotario Tomba in 1603, the great hospital dating from 1471, the library presented to the commune in 1846 by the marquis Ferdinando Landi, and the Passerini library founded in 1685. The Museo Civico, formed in 1903, contains collections of antiquities (though many of the Roman antiquities of Piacenza have passed to the museum of Parma), some good Flemish tapestries and a few pictures. The castle erected by Antonio da Sangallo the younger has been demolished. Piacenza is the junction of the Milan and Bologna line with that from Voghera and Turin. From Codogno, 7 m.
PIANOFORTE

559
to the north, a branch line runs to Cremona. By road Piacenza is 88 m. north-east of Genoa. The town has an arsenal, a technical and arts school, and various industries—iron and brass works, foundries, silk-throwing, printing works and flour-mills.

Piacenza was made a Roman colony in 218 B.C. While its walls were yet unfinished it had to repulse an attack by the Gauls, and in the latter part of 218 it afforded protection to the remains of the Roman army under Scipio which had been defeated in the great battle on the Trebia. In 205 it withstood a protracted siege by Hasdrubal. Five years later the Gauls burned the city; and in 190 it had to be recruited with three thousand families. In 187 it was connected with Ariminum and the south by the construction of the Via Aemilia. Later on it became a very important road centre; the continuation northwards of the Via Aemilia towards Milan, with a branch to Ticinum, crossed the Po there, and the Via Postumia from Cremona to Dertona and Genoa passed through it. Later still Augustus reconstructed the road from Dertona to Vade, and into Gallia Narbonensis, and gave it the name of Julia Augusta from Placentia onwards. The rectangular arrangement of the streets in the centre of the town, through which passes the Via Aemilia, is no doubt a survival from Roman times. Piacenza is mentioned in connexion with its capture by Cinna and a defeat of the forces of Carbo in the neighbourhood (82 B.C.), a mutiny of Julius Caesar's garrison (50 B.C.), another mutiny under Augustus (40 B.C.), the defence of the city by Spurinna, Otho's general, against Caecina, Vitellius's general (A.D. 69), and the defeat of Aurelian by the Marcomanni outside the walls (A.D. 271). In 546 Totila reduced Piacenza by famine. Between 909 and 1035 the city was governed by its bishops, who had received the title of count from Otho III. At Roncaglia, 5 m. to the east, the emperor Conrad II. held the diet which passed the Salic law. In the latter part of the 12th century it was one of the leading members of the Lombard League. For the most part it remained Guelph, though at times, as when it called in Galeazzo Visconti, it was glad to appeal to a powerful Ghibelline for aid against its domestic tyrants. In 1447 the city was captured and sacked by Francesco Sforza. Having been occupied by the papal forces in 1512, it was in 1545 united with Parma (q.v.) to form an hereditary duchy for Pierluigi Farnese, son of Paul III. In 1746 a battle between the Franco-Spanish forces and the Austrians was fought under the city walls, and in 1796 it was occupied by the French. In 1848 Piacenza was the first of the towns of Lombardy to join Piedmont; but it was reoccupied by the Austrians till 1850.

PIANOFORTE (Ital. piano, soft, and forte, loud). The group of keyed stringed musical instruments, among which the piano-forte is latest in order of time, has been invented and step by step developed with the modern art of music, which is based upon the simultaneous employment of different musical sounds. In the 17th century the "organum" arose, an elementary system of accompaniment to the voice, consisting of fourths and octaves below the melody and moving with it; and the organ (q.v.), the earliest keyed instrument, was, in the first instance, the rude embodiment of this idea and convenient means for its expression. There was as yet no keyboard of balanced key-levers; all the strings of the instrument were drawn out like modern draw-stops to admit the compressed air necessary to make the pipes sound. About the same time arose a large stringed instrument, the organistrum,¹ the parent of the now obsolete hurdy-gurdy; as the organ needed a blower as well as an organist, so the player of the organistrum required a hand-turner, by whose aid the three strings of the instrument were made to sound simultaneously upon a wheel, and, according to the well-known sculptured relief of St George de Boscherville, one string was manipulated by means of a row of stoppers or tangents pressed inwards to produce the notes. The other strings were drones, analogous to the drones of the bagpipes, but originally the three strings followed the changing organum.

In the 17th century, the epoch of Guido d'Arezzo, to whom the beginning of musical notation is attributed, the Pythagorean monochord, with its shifting bridge, was used in the singing schools to teach the intervals of the plain-song of the church. The practical necessity, not merely of demonstrating the proportionate relations of the intervals, but also of initiating pupils into the different gradations of the church tones, had soon after Guido's time brought into use quadruple-fashioned monochords, which were constructed with scales, analogous to the modern practice with thermometers which are made to show both Réâumur and Centigrade, so that four lines indicated as many authentic and as many plagal tones. This arrangement found great acceptance, for Aribio,² writing about fifty years after Guido, says that few monochords were to be found without it. Had the clavichord then been known, this make-shift contrivance would not have been necessary. Aribio strenuously deavoured to improve it, and "by the grace of God" invented a monochord measure which, on account of the rapidity of the leaps he could make with it, he named a wild-goat (capra). Jean de Muris (Musica speculativa, 1533) teaches how true relations may be found by a single-string monochord, but recommends a four-stringed one, properly a tetrachord, to gain a knowledge of unfamiliar intervals. He describes the musical instruments known in his time, but does not mention the clavichord or monochord with keys, which could not have been then invented. Perhaps one of the earliest forms of such an instrument, in which stoppers or tangents had been adopted from the organum, is shown in fig. 1, from a wood carving of a vicar choral or organist, preserved in St Mary's church, Shrewsbury. This is an instrument to which this interesting figure may be attributed c 1460, but the conventional representation shows that the instrument was then already of a past fashion, although perhaps still retained in use and familiar to the carver.

In the Weimar Wunderbuck,³ a MS. dated 1440, with pen and ink miniatures, is given a "clavichordium" having 8 short and apparently 16 long keys, the artist has drawn 12 strings in a rectangular case, but no tangents are visible. A keyboard of balanced keys existed in the little portable organ known as the regal, so often represented in old carvings, paintings and stained glass windows. Vitruvius (De Architectura, lib. x, cap. xi, translated by Newton, describes a balanced keyboard; but the key apparatus is more particularly shown in The Pneumatics of Hero of Alexandria, translated by Benet Woodcroft (London, 1851). In confirmation of this has been the remarkable recovery at Carlhage ⁴ of a terra-cotta model of a Hydraulikon or water organ, dating from the 2nd century A.D., in which a balanced keyboard of 18 or 19 keys is shown. It seems likely the balanced keyboard was lost, and afterwards reinvented. The name of

¹ An organistrum is shown in the lower right hand corner of the full page miniature of a fine 14th century psalter of English workmanship, forming part of the Hunterian collection in University Court Library, Glasgow. No. 31 in Catalogue of the Exhibition of Illuminated MSS. at the Burlington Fine Arts Club (1908).

⁴ For an illustration of this important piece of evidence, see under ORGAN; Ancient History; and for description and illustration of balanced keys, see KEYBOARD.
PIANOFORTE

regal was derived from the rule (regula) or graduated scale of keys, and its use was to give the singers in religious processions the note or pitch. The only instrument of this kind known to exist in the United Kingdom is at Blair Atholl, and it bears the very late date of 1630. The Brussels regal may be as modern. These are instances of how long a some-time admired musical instrument may remain in use after its first intention is forgotten. We attribute the adaptation of the narrow regal keyboard to what was still called the monochord, but was now a complex of monochords over one resonant board, to the latter half of the 14th century; it was accomplished by the substitution of tangents fixed in the future ends of the balanced keys for the movable bridges of the monochord or such stoppers as are shown in the Shrewsbury carving. Thus the monochordium or "payre of monochordis" became the clavichordium or "payre of clavicordis"—pair being applied, in the old sense of a "pair of steps," to a series of degrees. This use of the word to imply graduation was common in England to all keyed instruments; thus we read, in the Tudor period and later, of a pair of regals, organs, or virginals. Ed. van der Straeten reproduces a so-called clavichord of the 15th century from a MS. in the public library at Brussels. The treatise is anonymous, but other treatises in the same MS. bear dates 1503 and 1504. Van der Straeten is of opinion that the drawing may be assigned to the middle of the 15th century. The scribe calls the instrument a clavicimbalum, and this is undoubtedly correct; the 8 strings in the drawing are stretched from back to front over a long soundboard, the longest strings to the left; 8 keys, a long and a short with levers to which are attached the jacks, are seen in a horizontal line behind the keyboard, and behind them again are given the names of the notes a, b, c, d, e, f, g, h. In the Weimar Wunderbuch is a pen-and-ink sketch of the clavicimbalum placed upon a table, in which we recognize the familiar outline of the harpsichord, but on a smaller scale. The keyboard shows white and black notes—the latter short keys, one between each group of two white keys, precisely as in the instrument reproduced by Van der Straeten—but no mechanism is visible under the strings.

The earliest known record of the clavichord occurs in some rules of the minnesingers, dated 1404, preserved at Vienna. The monochord is named with it, showing a differentiation of these instruments, and of them from the clavicymbalum, the keyed cymbalum, cembalo (Italian), or psaltery. From this we learn that a keyboard had been early adapted to that favourite medieval stringed instrument, the "cembalo" of Boccaccio, the "sauterie" of Chaucer. There were two forms of the psaltery: (1) the trapeze, one of the oldest representations of which is to be found in Orcagna's famous Triomfo della Morte in the Campo Santo at Pisa, and another by the same painter in the National Gallery, London; and (2) the contemporary "testa di porco," the pig's head, which was of triangular shape as the name suggests. The trapeze psaltery was strung horizontally, the "istromento di porco" either horizontally or vertically— the notes, as in the common dulcimer, being in groups of three or four unisons. In these differences of form and stringing we see the earliest steps in the ultimate differentiation of the psaltery and harpsichord. The compass of the psalteries was nearly that of Guido's scale; but according to Mersenne, the lowest interval was a fourth, G to C, which is worthy of notice as anticipating the later "short measure" of the spinet and organ.

The simplicity of the clavichord inclines us to place it, in order of time, before the clavicymbalum or clavicimbalum; but we do not know how the sounds of the latter were at first excited. There is an indication as to its early form to be seen in the church of the Certosa near Pavia, which compares in probable date with

the Shrewsbury example. We quote the reference to it from Dr. Ambros.

1 See a carving represents King David as holding an "istromento di porco" which has eight strings and as many keys lying parallel to them; inside the body of the instrument, which is open at the side nearest the right hand of King David, he touches the keys with the right hand and damps the strings with the left. The attribution of archaisms applies with equal force to this carving as to the Shrewsbury one, for when the monastery of Certosa near Pavia was built by Ambrogio Fossana in 1472, chromatic keyboards, which imply a considerable advance, were already in use. There is an authentic representation of a chromatic keyboard, painted not later than 1426, in the St. Cecilia panel (now at Berlin) of the famous Adoration of the Lamb by the Van Eycks. The instrument depicted is a positive organ, and it is interesting to notice in this realistic painting that the keys are evidently boxwood, as in the Italian spinets of later date, and that the angel plays a common chord—A with the right hand, F and C with the left. But diatonic organs with eight steps or keys in the octave, which included the F flat and the B natural, as in Guido's scale, were long preserved, for Praetorius speaks of them as still existing nearly two hundred years later. This diatonic keyboard, we learn from Sebastian Virdung (Musica getutscht und ausgesogen, Basel, 1511), was the keyboard of the early clavichord. We reproduce his diagram as the only authority we have for the disposition of the one short key.

The extent of this scale is exactly Guido's. Virdung's diagram of the chromatic is the same as our own familiar keyboard, and comprises three octaves and a note, from F below the bass to G above the treble. But Virdung tells us that even then clavichords were made longer than four octaves by repetition of the same order of keys. The introduction of the chromatic order he attributes to the study of Boetius, and the consequent endeavour to restore the three musical genera of the Greeks—the diatonic, chromatic and enharmonic. But the last-named had not been attained. Virdung gives woodcuts of the clavichordum, the virginal, the clavicymbalum and the claviclytherium. We reproduce three of them (figs. 3, 6 and 12), omitting the virginal as obviously incorrect. Writers on musical instruments have continually repeated these drawings without discerning that in the printing they are reversed, which puts the keyboards entirely wrong, and that in Luscinii's Latin translation of Virdung (Musurgia, sive praxis musicae, Strasburg, 1536), which has been hitherto chiefly followed, two of the engraving, the clavicymbalum and the claviclytherium, are transposed, another cause of error. Martin Agricola (Musica instrumentalis, Witttenberg, 1520) has copied Virdung's illustrations with some differences of perspective, and the addition, here and there, of errors of his own.

7 Geschichte der Musik, ii. 544-555.
Still vulgarly known as monochord, Virdung's clavichord was really a box of monochords, all the strings being of the same length. He derives the clavichord from Guido's monochord as he does the virginal from the psaltery, but, at the same time, confesses he does not know when, or by whom, either instrument was invented. We observe in this drawing the short sound-board, which always remained a peculiarity of the clavichord, and the straight sound-board bridge—necessarily so when all the strings were of one length. To gain an angle of incidence for the tangents against the strings the keys were made crooked, an expedient further rendered necessary by the "fretting"—three tangents, according to Virdung, being directed to stop as many notes from each single group of three strings tuned in unison; each tangent thus made a different vibrating length of string. In the drawing the strings are merely indicated. The German for fret is Bund, and such a clavichord, in that language, is known as a "gebundenes Clavichord" both fret (to rub) and Bund (from binden, to bind) having been taken over from the lute or viol. The French and Italians employ "touche" and "tasto," touch. Praetorius who wrote a hundred years later than Virdung, says two, three and four tangents were thus employed in stopping. There are extant small clavichords having three keys and tangents to one pair of strings and others have no more than two tangents to a note formed by a pair of strings, instead of three. Thus seven pairs of strings suffice for an octave of twelve keys, the open notes being F, G, A, B flat, C, D, E flat, and by an unexplained peculiarity, perhaps derived from some special estimation of the notes which was connected with the church modes, A and D are left throughout free from a second tangent. A corresponding value of these notes is shown by their independence of chromatic alteration in tuning the double Irish harp, as explained by Vincentio Gallei in his treatise on music (Dialogo della musica, Florence, 1581). Adlung, who died in 1762, speaks of another fretting, but it must have been an adaptation to the modern major scale, the "fretted" notes being E and B. Clavichords were made with double fretting up to about the year 1700—that is to say, to the epoch of J. S. Bach, who, taking advantage of its abolition and the consequent use of independent pairs of strings for each note, was enabled to tune in all keys equally, which had been impossible so long as the fretting was maintained. The modern scales having become established, Bach was now able to produce, in 1722, Das wohltemperierte Clavier, the first collection of preludes and fugues in all the twenty-four major and minor modes for a clavichord which was tuned, as to concordance and dissonance, fairly equal.

The oldest clavichord, here called manicoardo (as French manicorde, from monochord), known to exist is that shown in fig. 4. It will be observed that the lowest octave is here already bridge, indispensable for the vibration, besides acting as the sound exciter (fig. 5). The common damper to all the strings is a list of cloth, interwoven behind the tangens. As the tangents quitted the strings the cloth immediately stopped all vibration. Too much cloth would diminish the tone of this already feeble instrument, which gained the name of "dumb spinet" from its use. In the clavichord in Rubens's St. Cecilia (Dresden Gallery)—interesting as perhaps representing the painter's own instrument—the damping cloth is accurately painted. The number of keys there shown is three octaves and a third, F to A—the same extent as in Handel's clavichord now in the museum at Maidstone (an Italian instrument dated 1726, and not fretted), but with the peculiarity of a combined chromatic and short octave in the lowest notes, to which we shall have to refer when we arrive at the spinet; we pass it by as the only instance we have come across in the clavichord.

The clavichord must have gone out of favour in Great Britain and the Netherlands early in the 16th century, before its expressive power, which is of the most tender and intimate quality, could have been, from the nature of the music played, observed,—the more brilliant and elegant spinet being preferred to it. Like the other keyboard instruments it had no German name, and can hardly have been of German origin. Holbein, in his drawing of the family of Sir Thomas More, 1528, now at Basel, indicates the place for "Klavikordi und ander Seytinspill." But it remained longest in use in Germany—until even the beginning of the 19th century. It was the favourite "Klavier" of the Bachs. Besides that of Handel already noticed there is in existence clavichords the former possession of which is attributed to Mozart and Beethoven. The clavichord was obedient to a peculiarity of touch possible on no other keyboard instrument. This is described by C. P. Emmanuel Bach in his famous essay on playing and accompaniment, entitled Versuch über die wahre Art das Klavier zu spielen ("An Essay on the True Way to play Keyboard Instruments.") It is the Bebung (trembling), a vibration in a melody note of the same nature as the tremolo frequently employed by violin players to heighten the expressive effect; it was gained by a repeated motion of the fleshy end of the finger while the key was still held down. The Bebung was indicated in the notation by dots over the note to be affected by it. According to the practice of the Bachs, as handed down to us in the above mentioned essay, great smoothness of touch was required to play the clavichord in tune. As with the monochord, the means taken to produce the sound disturbed the accuracy of the string measurement by increasing tension, so that a key touched too firmly in the clavichord, by unduly raising the string, sharpened the pitch, an error in playing depreciated by C. P. Emmanuel Bach. This answers the assertion which has been made that J. S. Bach could not have been nice about tuning when he played from preference on an instrument of uncertain intonation.

The next instrument described by Virdung is the virginal (virginalis, proper for a girl), a parallelogram in shape, having the same projecting keyboard and compass of keys the same as the clavichordium. Here we can trace derivation from the psaltery in the sound-board covering the entire inner surface of the instrument and in the triangular disposition of the strings. The virginal in Virdung's drawing has an impossible position with reference to the keyboard, which renders its reproduction as an illustration useless. But in the next drawing, the clavicimbalum, this is rectified, and the drawing, reversed on account of the keyboard, can be accepted as roughly representing the instrument so called (fig. 6). There would be...
no difference between it and the virginal were it not for a peculiar¬
arity of keyboard compass, which emphatically refers itself to the
Italian "spinet," a name unnoticed by Virdung or by his
countryman Arnold Schlick, who, in the same year 1511, pub¬
lished his Spiegel der Orgelmacher (Organ-builders' Mirror),
and named the clavicordium and clavicimbalum as familiar
instruments. In the first place, the keyboard, beginning appar¬
etly with B natural, instead of F, makes the clavicimbalum
smaller than the virginal, the strings in this arrangement being
shorter; in the next place it is almost certain that the Italian
spinet compass, beginning apparently upon a semitone, is
identical with a "short measure" or "short octave" organ
compass, a very old keyboard arrangement, by which the term
note, representing B, really sounded G and C sharp in like
manner A. The origin of this may be deduced from the psaltery
and many representations of the regal, and its object appears
to have been to obtain dominant basses for cadences, harmonious
closes having early been sought for as giving pleasure to the ear.
Authority for this practice is to be found in Mersenne, who, in
1636, expressly describes it as occurring in his own spinet
(espinette). He says the keyboards of the spinet and organ are
the same. Now, in his Latin edition of the same work he renders
earliest used we have no evidence. The little crow-quill points
project from centred tongues in uprights of wood known as
"jacks" (fig. 7), which also carry the dampers, and rising by
the depression of the keys in front, the quills set the strings
vibrating as they pluck them in passing, springs at first of steel,
later of bristle, giving energy to the twang and governing their
return. J. C. Scaliger in Poetics libri septem (1561, p. 51. e. 1.)
states that the Clavicimbalum and Harpichordum of his
boyhood are now called Spinetts on account of those quill
points (ab illis mucronulis), and attributes the introduction of
the name "spinetta" to them (from spina, a thorn). We
will leave harpichordum for the present, but the early identity
of clavicimbalum and spinetta is certainly proved.
Scaliger's etymology remained unquestioned until
Signor Ponsicci of Florence discovered another derivation.
He found in a rare book entitled Conclusione nel suono dell'
oraro, di D. Adriano Banchieri (Bologna, 1608), the following
passage, which translated reads: "Spinetta was thus named
from the inventor of that oblong form, who was one Maestro
Giovanni Spinetti, a Venetian; and I have seen one of
those instruments, in the possession of Francesco Storio,
organist of the magnificent community of Montagnana,
within which was this inscription—Joannes Spinettis Venetis
fecl, a.d. 1503." Scaliger's and Banchieri's statements may
be combined, as there is no discrepancy of dates, or we may
rely upon whichever seems to us to have the greater authority,
always bearing in mind that neither invalidates the other.
The introduction of crow-quill points, and adaptation to an oblong
case of an instrument previously in a trapèze form, are synchro-
nous; but we must accept 1503 as a late date for one of Spinetti's
instruments, seeing that the altered form had already become
common, as shown by Virdung, in another country as early as
1511. After this date there are frequent references to spinets in
public records and other documents, and we have fortunately the
instruments themselves to put in evidence, preserved in public
museums and in private collections. A spinet dated 1590
was shown at Bologna in 1888; another old spinet in the Conserva-
toire, Paris, is a pentagonal instrument made by Francesco di
Portapulis at Verona, 1523. The Milanese Rossi were famous
spinet-makers, and have been accredited (La Nobiltà di Milano,
1593) with an improvement in the form which we believe was
the recession of the keyboard, a feature which had previously
entirely projected; by the recession a greater width was obtained
for the sound-board. The spinets by Annibale Rosso at South
Kensington, dated respectively 1555 (fig. 8) and 1577, show this
alteration, and may be compared with the older and purer form
of one, dated 1568, by Marco Jada (also known as Marco "dalle
spinette," or "dai cembali"). Besides the pentagonal spinet,
there was an heptagonal variety; they had neither covers nor
stands, and were often withdrawn from decorated cases when
required for performance. In other instances, as in the 1577
Rosso spinet, the case of the instrument itself was richly adorned.
The apparent compass of the keyboard in Italy generally
exceeded four octaves by a semitone, E to F; but we may regard
the lowest natural key as usually C, and the lowest sharp key
as usually D, in these instruments, according to "short mesure."

The rectangular spinet, Virdung's "virginal," early assumed
in Italy the fashion of the large "cassoni" or wedding chests.
The oldest we know of in this style, and dated, is
the fine specimen belonging to M. Termé which
figures in L'Art décoratif (fig. 9). Virginal is not an Italian name;

---

1 A. J. Ellis (History of Musical Pitch, p. 318) sees the B in
Mersenne's outline diagram.
The rectangular instrument in Italy is "spinetta tavola." In England, from Henry VII. to Charles II., all quilled instruments (stromenti di penne), without distinction as to form, were known as virginals. It was a common name, equivalent to the contemporary Italian clavicordo and Flemish clavizensig. From the latter, by apocope, we arrive at the French clavecin—the French claveir (clavix, a key), a keyboard, being in its turn adopted by the Germans to denote any keyboard stringed instrument. The spinets of Keene and Player, made about 1700, have from two to two and a half scales on the left hand end of the keyboard, as in the description by Mersenne, quoted above, of a spinet with short measure. Such divided sharps have been assumed to be quarter tones, but enharmonic intervals in the extreme bass can have no justification. From the tuning of Handel's Italian clavicord already mentioned, which has this peculiarity, and from Praetorius we find the further halves of the two divided sharps were the chromatic semitones, and the nearer halves the major thirds below i.e. the dominant fourths to the next natural keys. Thomas Hitchcock (for whom there are dates 1664 and 1705 written on keys and jacks of spinets bearing Edward Blunt's name and having divided bass sharps) made a great advance in constructing spinets, giving them the wide compass of five octaves, from G to G, with very fine keyboards in which the sharps were inlaid with a slip of the ivory or ebony, as the case might be, of the naturals. Their instruments, always numbered, and not dated as has been sometimes supposed, became models for contemporary and subsequent English makers.

We have now to ask what was the difference between Scarliger's harpsichordum and his clavicymbal. Galilei, the father of the astronomer of that name (Dialogo della musica antica e moderna, Florence, 1581), says that the harpsichord was so named from having resembled an "arpa glanscet," a prostrate or "couchèd" harp, proving that the clavicymbal was at first the trapeze shaped spinet; and we should therefore consider the harpsichord and clavicymbal as, in form, suggested by or derived from the harp and psalterie, or from a "testa di porco" and an ordinary trapeze psalterie. We are inclined to prefer the latter. The Latin name "clavicymbalum," having early been replaced by spinet and virginal, was in Italy and France bestowed upon the long harpsichord, and was continued as claviecembalo (gravecembalo, or familiarly cembalo only) and clavecin. Much later, after the restoration of the Stuarts, the first name was accepted and naturalized in England as harpsichord, which we will define as the long instrument with quills, shaped like a modern grand piano, and resembling a wing, from which it has gained the German appellation "Flügel." We can point out no long instrument of this kind so old as the Roman cembalo at South Kensington (fig. 11). It was made by Geronimo of Bologna in 1521, two years before the Paris Porta-lupis spinet. The outer case is of finely tooled leather. It has a spinet keyboard with a compass of nearly four octaves, E to D. The natural keys are of boxwood, gracefully arched in front. The keyboard of the Italian cembalo was afterwards carried out to the normal four octaves. There is an existing example, dated 1656, with the bass keys carried out without sharps in long measure (unfortunately altered by a restorer with silvers). It is surprising to see with what steady persistence the Italians adhered to their original model in making the instrument. As late as the epoch of Cristofori, and in his 1722 cembalo at Florence, we still find the independent outer case, the single keyboard, the two unisons, without power to reduce to one by using stops. The Italians have been as conservative with their forms of spinet, and are to this day with their organs. The startling "piano e forte" of 1598, brought to light from the records of the house of D'Este by Count Valdrighi of Modena, after much consideration and a desire to find in it an anticipation of Cristofori's subsequent invention of the pianoforte, we are disposed to regard as an ordinary cembalo with power to shift, by a stop,

In the harpsichord Cristofori made for Prince Ferdinando dei Medici in 1702, recently acquired by Mr. Stearns, of Detroit, and presented by him to the University of Michigan, U.S.A., there are three keyboards, thus arranged: 1st, highest keyboard, octave string only, mid-lever, and first unison; 2nd, first and second unisons; 3rd, second and third unisons. A harpsichord similarly designed with three keyboards, inscribed "Vincentius Sodi Florentinus Fecit, Anno Domini 1779," was presented by Mrs. J. Crosby Brown to the Metropolitan Museum, New York.

3 In the Kraus Museum Catalogue (1901), No. 559.

4 See Van der Straeten, vi. 122.
from two unisons (forte) to one string (piano), at that time a Flemish practice, and most likely brought to Italy by one of the Flemish musicians who founded the Italian school of composition. About the year 1600, when accompaniment was invented for monody, large cembalos were made for the orchestras to bring out the bass part, the performer standing to play. Such an instrument was called "archicembalo," a name also applied to a large cembalo, made by Vito Trasuntino, a Venetian, in 1606, intended by thirty-one keys in each of its four octaves—one hundred and twenty-five in all—to restore the three genera of the ancient Greeks. How many attempts have been made before and since Trasuntino to purify intonation in keyboard instruments by multiplying keys in the octave? Simultaneously with Father Smith's well-known experiment in the Temple organ, London, there were divided keys in an Italian harpsichord to gain a separate G sharp and A flat, and a separate D sharp and E flat.

Double keyboards and stops in the long cembalo or harpsichord came into use in the Netherlands early in the 16th century. We find them imported into England. The following citations, quoted by Rimbault in his History of the Pianoforte, but imperfectly understood by him, are from the pryv purse expenses of King Henry VIII., as extracted by Sir Harris Nicolas in 1827.

"1530 (April). Item the vj daye paid to William Lewes for ii paire of virginals in one coffer with iill stopps brought to Grenewiche iii li. And for ii paire of virginals in one coffer brought to the More other iii li."

Now the second instrument may be explained, virginals meaning any quilled instrument, as a double spinet, like that at Nuremberg by Martin van der Beest, the octave division being movable. But the first cannot be so explained; the four stops can only belong to a harpsichord, and the two pair instrument to a double-keyed one, one keyboard being over, and not by the side of the other. Again from the inventory after the king's death (see Brit. Mus. Har. MS. 1410) fol. 247—

"Two fair pair of new long Virginalles made harp-fashion of Cipres, with keys of ivory, having the King's Arms crowned and supported by his Grace's beasts within a garnet gilt, standing over the keys."

We are disposed to believe that we have here another double keyboard harpsichord. Rimbault saw in this an upright instrument, such as Virdung's clavicytherium (fig. 12). Having since seen the one in the Kraus Muscum, Florence, it seems that Virdung's drawing should not have been reversed; but he has mistaken the wires acting upon the jacks for strings, and omitted the latter stretched horizontally across the soundboard (see CLAVICYTHERIUM). We read in an inventory of the furniture of Warwick Castle, 1584, "a faire paire of double virginalles," and in the Hengrave inventory, 1603, "one great payre of double virginalles." Hans Ruckers, the great clavisingel maker of Antwerp, lived too late to have invented the double keyboard and stops, evident adoptions from the organ, and the octave string (the invention of which was so long attributed to him), which incorporated the octave spinet with the large instrument, to be henceforth playable without the co-operation of another performer, was already in use when he began his work.

Until the last harpsichord was made by Joseph Kirkman, in 1798, scarcely an instrument of the kind was constructed, except in Italy, without the octaves. The harpsichord as known throughout the 18th century, with piano upper and forte lower keyboard, was the invention of Hans Ruckers' grandson, Jean Ruckers' nephew, Jan Couchet, about 1640. Before that time the double keyboards in Flemish harpsichords were merely a transposing expedient, to change the pitch a fourth, from plagal to authentic and vice versa, while using the same groups of keys. Fortunately there is a harpsichord existing with double keyboards unaltered, date 1638, belonging to Sir Bernard Samuelson, formerly in the possession of Mr Spence, of Florence, made by Jean Ruckers, the keyboards being in their original position. It was not so much invention as beauty of tone which made the Ruckers' harpsichords famous. The Ruckers harpsichords in the 18th century were fetching such prices as Bologna luttes did in the 17th or Cremona violins do now. There are still many specimens existing in Belgium, France and England. Handel had a Ruckers harpsichord, now in Buckingham Palace; it completes the number of sixty-three existing Ruckers instruments catalogued in Grove's Dictionary of Music and Musicians.

After the Antwerp make declined, London became pre-eminent for harpsichords—the representative makers being Jacob Kirckmann and Burckhard Tschudi, pupils of a Flemish master, one Tabel, who had settled in London, and whose business Kirckmann continued through marriage with Tabel's widow. Tschudi was of a noble Swiss family belonging to the canton of Glarus. According to the custom with foreign names obtaining at that time, by which Hacnel became Handel, and Schmidt Smith, Kirckmann dropped his final n and Tschudi became Shudi, but he resumed the full spelling in the faces of the splendid harpsichords he made in 1766 for Frederick the Great, which are still preserved in the New Paheae, Potsdam. By these great makers the harpsichord became a larger, heavier-strung and more powerful instrument, and fancy stops were added to vary the tone effects. To the three shifting registers of jacks of the octave and first and second unisons were added the "lute," the charm of which was due to the favouring of high harmonies by plucking the strings close to the bridge, and the "harp," a surdine or muting effect produced by impeding the vibration of the strings by contact of small pieces of buff leather. Two pedals were also used, the left-hand one a combination of a unison and lute. This pedal, with the "machine" stop, reduced the upper keyboard to the lute register, the plectra of which acted upon the strings near the wrest-plank bridge.

---

1 Invented by Nicola Vicentino; see L'Antica musica ridotta alla moderna pratica (Rome, 1555).
only; the lower keyboard to the second unison. Releasing the machine stop and quitting the pedal restores the first unison on both keyboards and the octave on the lower. The right-hand pedal was to raise a hinged portion of the top or cover and thus gain some power of "swell" or crescendo, an invention of Roger Plenius, to whom also the harp stop may be rightly attributed. This ingenious harpsichord maker had been stimulated to gain these effects by the nascent pianoforte which, as we shall find, he was the first to make in England. The first idea of pedals for the harpsichord to act as stops appears to have been John Hayward's ("Haward") as early as 1676, as we learn from Mace's *Music's Monument*, p. 235. The French makers preferred a kind of knee-pedal arrangement, known as the "genouillère," and sometimes a more complete muting by one long strip of buff leather, the "sourdine." As an improvement upon Plenius's clumsy swell, Shudi in 1769 patented the Venetian swell, a framing of louvres, like a Venetian blind, which opened by the movement of the pedal, and becoming in England a favourite addition to harpsichords, was early transferred to the organ, in which it replaced the rude "nag's-head" swell. A French harpsichord maker, Marius, whose name is remembered from a futile attempt to design a pianoforte action, invented a folding harpsichord, the "clavecín brisé," by which the instrument could be disposed of in a smaller space. One, which is preserved at Berlin, probably formed part of the camp baggage of Frederick the Great.

It was formerly a custom with kings, princes and nobles to keep large collections of musical instruments for actual playing purposes, in the domestic and festive music of their courts. There are records of their inventories, and it was to keep such a collection in playing order that Prince Ferdinand dei Medici engaged a Paduan harpsichord maker, Bartolommeo Cristofori, the man of genius who invented and produced the pianoforte.  

We fortunately possess the record of this invention in a literary form from a well-known writer, the Marchese Scipione Maffei; his description appeared in the *Giornale dei letterati d'Italia*, a publication conducted by Apostolo Zeno. The date of Maffei's paper was 1711. Rimbault reproduced it, with a technically imperfect translation, in his *History of the Pianoforte*. We learn from it that in 1709 Cristofori had completed four grand cembali col piano e forte—the keyed-psalteries with soft and loud—three of them being of the long or independent psaltery form. A synonymy in Italian for the original cembalo (or psalter) is "salterio," and if it were struck with hammers it became a "salterio tedesco" (the German hackbrett, or chopping board), the latter being the common dulcimer. Now the first notion of a pianoforte is a dulcimer with keys, and we may perhaps not be wrong in supposing that there had been many attempts and failures to put a keyboard to a dulcimer or harpsichord before Cristofori successfully solved the problem. The sketch of his action in Maffei's essay shows an incomplete stage in the invention, although the kernel of it—the principle of escapement or the controlled rebound of the hammer—is already there. He claims it to have been the "voglia mobile" or hopper, working, when the key is depressed by the touch, in a small projection from the central hammer-butt. The return, governed by a spring, must have been uncertain and incapable of further regulating than could be obtained by modifying the strength of the spring.

Moreover, the hammer had each time to be raised the entire distance of its fall. There are, however, two pianofortes by Cristofori, dated respectively 1720 and 1726, which show a much improved, we may even say a perfected, construction, for the whole of an essential piano movement is there. The earlier instrument (now in the Metropolitan Museum, New York) has undergone considerable restoration, the original hollow hammer-head having been replaced by a modern one, and the hammer-butt, instead of being centred by means of the holes provided by Cristofori himself for the purpose, having been lengthened by a leather hinge screwed to the block; but the 1726 one, which is in the Kraus Museum at Florence, retains the original leather hammer-heads. Both instruments possess alike a contrivance for determining the radius of the hopper, and both have been unexpectedly found to have the "check" (Ital. *paramartello*), which regulates the fall of the hammer according to the strength of the blow which has impelled it to the strings. After this discovery of the actual instruments of Cristofori there can be no longer doubt as to the attribution of the invention to him in its initiation and its practical completion with escapement and check. To Cristofori we are indebted, not only for the power of playing *piano* and *forte*, but for the infinite variations of tone, or *nuances*, which render the instrument so delightful.

But his problem was not solved by the devising of a working action; there was much more to be done to install the pianoforte as a new musical instrument. The resonance, that most subtle

**PIANOFORTE**

**Cristofori's Invention of the Pianoforte.**

We learn from Maffei's essay that in 1709 Cristofori had completed four grand cembali col piano e forte—the keyed-psalteries with soft and loud—the first three of them being of the long or independent psaltery form. A synonymy in Italian for the original cembalo (or psalter) is "salterio," and if it were struck with hammers it became a "salterio tedesco" (the German hackbrett, or chopping board), the latter being the common dulcimer. Now the first notion of a pianoforte is a dulcimer with keys, and we may perhaps not be wrong in supposing that there had been many attempts and failures to put a keyboard to a dulcimer or harpsichord before Cristofori successfully solved the problem. The sketch of his action in Maffei's essay shows an incomplete stage in the invention, although the kernel of it—the principle of escapement or the controlled rebound of the hammer—is already there. He claims it to have been the "voglia mobile" or hopper, working, when the key is depressed by the touch, in a small projection from the central hammer-butt. The return, governed by a spring, must have been uncertain and incapable of further regulating than could be obtained by modifying the strength of the spring.

and yet all-embracing factor, had been experimentally developed to a certain perfection by many generations of spinet and harpsichord makers, but the resistance structure had to be thought out again. Thicker stringing, rendered indispensable to withstand even Cristofori's light hammers, demanded in its turn a stronger framing than the harpsichord had needed. To make his structure firm he considerably increased the strength of the block which holds the tuning-pins, and as he could not do so without materially adding to its thickness, he adopted the bold expedient of inverting it; driving his wrest-pins, harp-fashion, through it, so that tuning was effected at their upper, while the wires were attached to their lower ends. Then, to guarantee the security of the case, he ran an independent string-block round it of stouter wood than had been used in harpsichords, in which block the hitch-pins were driven to hold the farther ends of the strings, which were spaced at

Communicated by Baron Alexander Kraus (May 1908).
equal distances (unlike the harpsichord), the dampers lying between the pairs of unisons.

Cristofori died in 1731. He had pupils, but did not found a school of Italian pianoforte-making, perhaps from the peculiar Italian conservatism in musical instruments we have already remarked upon. The essay of Scipione Maffei was translated into German, in 1725, by König, the court poet at Dresden, and friend of Gottfried Silbermann, the renowned organ builder and harpsichord and clavichord maker. Incited by this publication, and perhaps by having seen in Dresden one of Silbermann's Cristofori's pianofortes, Silbermann appears to have taken up the new instrument, and in 1726 to have manufactured two, which J. S. Bach, according to his pupil Agricola, pronounced failures. The trebles were too weak; the touch was too heavy. There has long been another version to this story, viz. that Silbermann borrowed the idea of his action from a very simple model contrived by a young musician named Schroeter, who had left it at the electoral court in 1721, and, quitting Saxony to travel, had not afterwards claimed it. It may be so; but Schroeter's letter, printed in Mitzler's Bibliothek, dated 1738, is not supported by any other evidence than the recent discovery of an altered German harpsichord, the hammer action of which, in its simplicity, may have been taken from Schroeter's diagram, and would sufficiently account for the condemnation of Silbermann's earliest pianofortes if he had made use of it. In either case it is easy to distinguish between the lines of Schroeter's interesting communications (to Mitzler, and later to Marpurg) the latter disappointment he felt in being left out of the practical development of so important an instrument.

But, whatever Silbermann's first experiments were based upon, it was ascertained, by the investigations of A. J. Hipkins, that he, when successful, adopted Cristofori's pianoforte without further alteration than the compass and colour of the keys and the style of joinery of the case. In the Silbermann grand pianofortes, in the three palaces at Potsdam, known to have been Frederick the Great's, and to have been acquired by that monarch prior to J. S. Bach's visit to him in 1747, we find the Cristofori framing, stringing, inverted wrest-plank and action complete. Fig. 15 represents the instrument on which J. S. Bach played in the Town Palace, Potsdam.

Fig. 15.—Silbermann Forte Piano; Stadtschloss, Potsdam, 1746.

It has been repeatedly stated in Germany that Frederici, of Gera in Saxony, an organ builder and musical instrument maker, invented the square or table-shaped piano, the "forte," as he is said to have called it, about 1755–1760. No square piano by this maker is forthcoming, though an "upright grand" piano, made by Domenico del Mela in 1739, with an action adapted from Cristofori's has been discovered by Signor Ponsichii of Florence. Victor

\[\text{At least one digit has been omitted due to underflow.}\]

\[\text{See Cesare Ponsichii, } \text{II Pianoforte, sua origine e sviluppo} \text{ (Florence, 1876), p. 37.}\]

\[\text{This translation, published at Hamburg and reproduced in } \text{extenso, may be read in Dr Oscar Paul's } \text{Geschichte des Claviers} \text{ (Leipzig, 1868).}\]
almost illegible. Paul de Wit refers the instrument to the middle of the 18th century. It has all the appearance of being a reduced copy of a well-established type, differing very little from the later models, except that it has no dampers. It seems probable that this small instrument is a converted clavichord, and that the action may have been suggested by Schroeter's model, left in 1721 at the Electoral Court of Saxony. Burney tells us all about Zumpe; and his instruments still existing would fix the date of the first at about 1765. Fetis narrates, however, that he began the study of the piano on a square piano made by Zumpe in 1762. In his simple "old man's head" action we have the nearest approach to a realization of Schroeter's simple idea. It will be observed that Schroeter's damper would stop all vibration at once. This defect is overcome by Zumpe's "nipple stick" damper.

Another piano action had, however, come into use about that time or even earlier in Germany. The discovery of it in the simplest form is to be attributed to V. C. Mahillon, who found it in a square piano belonging to Henri Gosselin, painter, of Brussels. The principle of this action is that which was later perfected by the addition of a good escapement by Stein of Augsburg, and was again later experimented upon by Sebastian Erard. Its origin is perhaps due to the contrivance of a piano action that should suit the shallow clavichord and permit of its transformation into a square piano; a transformation, Schroeter tells us, had been going on when he

![Fig. 18. Schroeter's Model for an Action, 1721.](image)

wrote his complaint. It will be observed that the hammer is, as compared with other actions, reversed, and the axis rises with the key, necessitating a fixed means for raising the hammer, in this action effected by a rail against which the hammer

![Fig. 19. Zumpe's Square Piano Action, 1766.](image)

is jerked up. It was Stein's merit to graft the hopper principle upon this simple action; and Mozart's approbation of the invention, when he met with it at Augsburg in 1777, is expressed in a well-known letter addressed to his mother. No more "blocking" of the hammer, destroying all vibration, was henceforth to vex his mind. He had found the instrument that for the rest of his short life replaced the harpsichord. V. C. Mahillon secured for his museum the only Johann Andreas Stein piano which

![Fig. 20. Old Piano Action on the German principle of Escape-ment. Square Piano belonging to M. Gosselin, Brussels.](image)

is known to remain. It is from Augsburg, dated 1780, and has Stein's escape action, two unisons, and the knee pedal, then and later common in Germany.

Mozart's own grand piano, preserved at Salzburg, and the two grand pianos (the latest dated 1790), by Hahn of Berlin, preserved at Berlin and Charlottenburg, because they had

![Fig. 21. Stein's Action (the earliest so-called Viennese), 1780.](image)

belonged to Queen Luise of Prussia, follow Stein in all particulars. These instruments have three unisons upwards, and the muting movement known as celeste, which no doubt Stein had also. The wrest-plank is not inverted; nor is there any imitation of Cristofori. We may regard Stein, coming after the Seven Years' War which had devastated Saxony, as the German reinventor of the grand piano. Stein's instrument was accepted as a model, as we have seen, in Berlin as well as Vienna, to which city his business was transferred in 1794 by his daughter Nanette, known as an accomplished pianist and friend of Beethoven, who at that time used Stein's pianos. She had her brother in the business with her, and had already, in 1793, married J. A. Streicher, a pianist from Stuttgart, and distinguished as a personal friend of Schiller. In 1802, the brother and sister dissenting partnership, Streicher began himself to take his full share of the work, and on Stein's lines improved the Viennese instrument, so popular for many years and famous for its lightness of touch, which contributed to the special character of the Viennese school of pianoforte playing. Since 1862, when Steinway's example caused a complete revolution in German and Austrian piano-making, the old wooden cheap grand piano has died out. We will quit the early German piano with an illustration (fig. 22) of an early square piano action in an instrument made by Johann Gottlob Wagner of Dresden in 1783. This interesting discovery of Mahillon's introduces us to a rude imitation (in the principle) of Cristofori, and it appears to have no relation whatever to the clock-hammer motion seen in Frederici's.

Burney, who lived through the period of the displacement of the harpsichord by the pianoforte, is the only authority to whom we can refer as to the introduction of the latter instrument into England. He tells us, in his gossiping way, that the first hammer harpsichord that came to England was made by an English monk at Rome, a Father Wood, for an English gentleman, Samuel Crisp of Chevington; the tone of this instrument was superior to that produced by quills, with the added power of the shades of piano and forte, so that, although the touch and mechanism were so imperfect that nothing quick could be executed upon it, yet in a slow movement like the "Dead March" in Saul it excited wonder and delight. Fulke Greville afterwards bought this instrument for 100 guineas, and it remained unique in England for several years, until Plenius, the inventor of the lyrechord, made a pianoforte in imitation of it. In this instrument the touch was better, but the tone was inferior. We have no date for Father Wood. Plenius produced his lyrechord, a sostenente

PIANOFORTE

harpsichord, in 1745. When Mason imported a pianoforte in 1755, Fulke Greville's could have been no longer unique. The Italian origin of Father Wood's pianoforte points to a copy of Cristofori, but the description of its capabilities in no way confirms this supposition, unless we adopt the very possible theory that the instrument had arrived out of order and there was on one in London who could put it right, or would perhaps divine that it was wrong. Burney further tells us that the arrival in London of J. C. Bach in 1759 was the motive for several of the second-rate harpsichord makers trying to make pianofortes, but with no particular success. Of these Americus Backers (d. 1776), said to be a Dutchman, appears to have gained the first place. He was afterwards the inventor of the so-called English action, and as this action is based upon Cristofori's we may suppose he at first followed Silbermann in copying the original inventor.

There is an old play-bill of Covent Garden in Messrs Broadwood's possession dated the 16th of May 1797, which has the following announcement:— "End of Act 1. Miss Brickle will sing a favourite song from Judith, accompanied by Mr Dibdin on a new instrument call'd Piano Forte."

The mind at once reverts to Backers as the probable maker of this novelty. Backers's "Original Forte Piano" was played at the Thatched House in St James's Street, London, in 1773. Ponsicchi has found a Backers grand piano at Pistoria, dated that year. It was Backers who produced the action continued in the direct principle by the firm of Broadwood, or with the reversed lever and hammer-butt introduced by the firm of Collard in 1835.

The escapement lever is suggested by Cristofori's first action, to which Backers has added a contrivance for regulating it by means of a button and screw. The check is from Broadwood; Cristofori's second action. No more durable action has been constructed, and it has always been found equal, whether made in England or abroad, to the demands of the most advanced virtuosi. John Broadwood and Robert Stodart were friends, Stodart having been Broadwood's pupil; and they were the assistants of Backers in the installation of his invention. On his deathbed he commended it to Broadwood's care, but Stodart appears to have been the first to advance it—Broadwood being probably held back by his partnership with his brother-in-law, the son of Shudi, in the harpsichord business. (The elder Shudi had died in 1773.) Stodart soon made a considerable reputation with his "grand" pianofortes, a designation he was the first to give them. In Stodart's grand piano we first find an adaptation from the lyre-chord of Plinius, of steel arches between the wrest-plank and belly-rail, bridging the gap up which the hammers rise, in itself an important cause of weakness. These are not found in any contemporary German instruments, but may have been part of Backers's.

Imitation of the harpsichord by "octaving" was at this time an object with piano makers. Zumpe's small square piano had met with great success; he was soon enabled to retire, and his imitators, who were legion, continued his model with its hand stops for the dampers and sordine, with little change but that which straightened the keys from the divergences inherited from the clavicord. John Broadwood took this domestic instrument first in hand to improve it, and in the year 1780 succeeded in entirely reconstructing it. He transferred the wrest-plank and pins from the right-hand side, as in the clavicord, to the back of the case, an improvement universally adopted after his patent, No. 1379 of 1789, expired. In this patent we first find the damper and piano pedals, since universally accepted, but at first in the grand pianofortes only. Zumpe's action remaining with an altered damper, another inventor, John Geib, patented (No. 1571 of 1786) the hopper with two separate escapements, one of which soon became adopted in the grasshopper of the square piano, it is believed by Geib himself; and Petzold, a Paris maker, appears to have taken later to the escapement effected upon the key. We may mention here that the square piano was developed and continued in England until about the year 1860, when it went out of fashion.

To return to John Broadwood—having launched his reconstructed square piano, he next turned his attention to the grand piano to continue the improvement of it from the point where Backers had left it. The grand piano was in framing and resonance entirely on the harpsichord principle, the sound-board bridge being still continued in one undivided length. The strings, which were of brass wire in the bass, descended in notes of three unisons to the lowest note of the scale. Tension was left to chance, and a reasonable striking line or place for the hammers was not thought of. Theory requires that the notes of octaves should be multiples in the ratio of 1 to 2, by which, taking the treble clef C at one foot, the lowest F of the five-octave scale would require a vibrating length between the bridges of 12 ft. As only half this length could be conveniently afforded, we see at once a reason for the above-mentioned deficiencies. Only the three octaves of the treble, which had lengths practically ideal, could be tolerably adjusted. Then the striking-line, which should be at an eighth or not less than a ninth or tenth of the vibrating length, and had never been cared for in the harpsichord, was in the lowest two octaves out of all proportion, with corresponding disadvantage to the tone. John Broadwood did not venture alone upon the path.

FIG. 25.—Collard's Grand Piano Action, 1884. English action, with reversed hopper and contrivance for repetition added.
towards rectifying these faults. He called in the aid of skilled men of science—Tiberius Cavallo, who in 1788 published his calculations of the tension, and Dr Gray, of the British Museum. The problem was solved by dividing the sound-board bridge, the lower half of which was advanced to carry the bass strings, which were still of brass. The first attempts to equalize the tension and improve the striking-place were here set forth, to the great advantage of the instrument, which in its wooden construction might now be considered complete. The greatest pianists of that epoch, except Mozart and Beethoven, were assembled in London—Clementi, who first gave the pianoforte its own character, raising it from being a mere variety of the harpsichord, his pupils Cramer and for a time Hummel, later on John Field, and also the brilliant virtuosi Dussek and Steibelt. To please Dussek, Broadwood in 1791 carried his five-octave, F to F, keyboard, by adding keys upwards, to five and a half octaves, F to C. In 1794 the additional bass half octave to C, which Shudi had first introduced in his double harpsichords, was given to the piano. Steibelt, while in England, instituted the familiar signs for the employment of the pedals, which owes its charm to excitement of the imagination instigated by power over an acoustical phenomenon, the sympathetic vibration of the strings. In 1799 Clementi founded a pianoforte manufactory, to be subsequently developed and carried on by Messrs Collard.

The first square piano made in France is said to have been constructed in 1776 by Sebastian Erard, a young Alsatian. In 1796 he came to England and founded the London manufactory of harps and pianofortes bearing his name. That eminent mechanic and inventor is said to have at first adopted for his pianos the English models.

**Fig. 26.**—Erard’s Double Escapement Action, 1884. The double escapement or repetition is effected by a spring in the balance pressing the hinged lever upwards, to allow the hammer which delivers the blow to return to its position under the nose of the hammer, before the key has risen again.

However, in 1794 and 1801, as is shown by his patents, he was certainly engaged upon the elementary action described as appertaining to Gosselin’s piano, of probably German origin. In his long-continued labour of inventing and constructing a double escapement action, Erard appears to have sought to combine the English power of gradation of tone with the German lightness of touch. He took out his first patent for a “repitition” action in 1806, claiming for it “the power of giving repeated strokes without missing or failure, by very small angular motions of the key itself.” He did not, however, succeed in producing his famous repetition or double escapement action until 1821; it was then patented by his nephew Pierre Erard, who, when the patent expired in England in 1835, proved a loss from the difficulties of carrying out the invention, which induced the House of Lords to grant an extension of the patent.

Erard invented in 1888 an upward bearing to the wrest-plank bridge, by means of agrafes or studs of metal through holes in which the strings are made to pass, bearing against the upper side. The wrest-plank bridge with down-bearing strings is clearly not in relation with upward-striking hammers, the tendency of which must be to raise the strings from the bridge, to the detriment of the tone. A long brass bridge on this principle was introduced by William Stodart in 1822. A pressure-bar bearing of later introduction is claimed for the French maker, Bord. The first to see the importance of iron sharing with wood (ultimately almost supplanting it) in pianoforte framing was a native of England and a civil engineer by profession, John Isaac Hawkins, known as the inventor of the ever-pointed pencil. He was living at Philadelphia, U.S.A., when he invented and first produced the familiar cottage pianoforte—"portable grand" as he then called it. He patented it in America, his father, Isaac Hawkins, taking out the patent for him in England in the same year, 1800. It will be observed that the illustration here given (fig. 26) represents a wreck; but a draughtsman’s restoration might be open to question.

There had been upright grand pianos as well as upright harpsichords, the horizontal instrument being turned up upon its wider end and a keyboard and action adapted to it. William Southwell, an Irish piano-maker, had in 1798 tried a similar experiment with a square piano, to be repeated in later years by W. F. Collard of London; but Hawkins was the first to make a piano, or pianino, with the strings descending to the floor, the keyboard being raised, and this, although at the moment the chief, was not his only merit. He anticipated nearly every discovery that has since been introduced as novel. His instrument (fig. 28) is in a complete iron frame, independent of the case; and in this frame, strengthened by a system of iron resistance rods combined with an iron upper bridge, his sound-board is entirely suspended. An apparatus for tuning by mechanical screws regulates the tension of the strings, which are of equal length throughout. The action, in metal supports, anticipates Wornum’s in the checking, and still later ideas in a contrivance for repetition. This remarkable bundle of inventions was brought to London and exhibited by Hawkins himself:

**Fig. 27.**—Steinway’s Grand Piano Action, 1884. The double escapement as in Erard’s, but with shortened balance and usual check.

**Fig. 28.**—Hawkins’s Portable Grand Piano, 1800. An upright instrument, the original of the modern cottage piano or pianino. In Messrs Broadwood’s museum and unrestored.
but the instrument being poor in the tone failed to bring him pecuniary reward or the credit he deserved. Southwell appears to have been one of the first to profit by Hawkins's ideas by bringing out the high cabinet pianoforte, with hinged sticker action, in 1807. All that he could, however, patent in it was the simple damper action, turning on a pivot to relieve the dampers from the strings, which is still frequently used with such actions. The next steps for producing the lower or cottage upright piano were taken by Robert Wornum, who in 1811 produced a diagonally, and in 1813 a vertically, strung one. Wornum's perfected crank action (fig. 29) was not complete until 1826, when it was patented for a cabinet piano; but it was not really introduced until three years later, when Wornum applied it to his little "piccolo." The principle of this centred lever check action was introduced into Paris by Pleyel⁴ and Pape, and thence into Germany and America.

It was not, however, from Hawkins's invention that iron became introduced as essential to the structure of a pianoforte. This was due to William Allen, a young Scotsman in the employ of the Stodarts. He devised a metal system of framing intended primarily for compensation, but soon to become, in other hands, a framing for resistance. His idea was to meet the divergence in tuning caused in brass and iron strings by atmospheric changes by compensating tubes and plates of the same metals, guaranteeing their stability by a cross batoning of stout wooden bars and a metal bar across the wrest-plank. Allen, being simply a tuner, had not the full practical knowledge for carrying out the idea. He had to ally himself with Stodart's foreman, Thorn; and Allen and Thom patented the invention in January 1820. The firm of Stodart at once acquired the patent.

We have now arrived at an important epoch in pianoforte construction—the abolition, at least in England and France, of the wooden construction in favour of a combined construction of iron and wood, the former material gradually asserting pre-eminence. Allen's design is shown in fig. 30. The long bars shown in the diagram are really tubes fixed at one end only; those of iron lie over the iron or steel wire, while those of brass lie over the brass wire, the metal plates to which they are attached being in the same correspondence. At once a great advance was made in the possibility of using heavier strings than could be stretched before, without danger to the durability of the case and frame. The next step was in 1821, to a fixed iron string-plate, the invention of one of Broadwood's workmen, Samuel Hervé, which was in the first instance applied to one of the square pianos of that firm. The great advantage in the fixed plate was a more even solid counterpoise to the drawing or tension of the strings and the abolition of their undue length behind the bridge, a reduction which Isaac Carter⁴ had tried some years before, but unsuccessfully, to accomplish with a plate of wood. So generally was attention now given to improved methods of resistance that it has not been found possible to determine who first practically introduced those long iron or steel resistance bars which are so familiar a feature in modern grand pianos. They were experimented on as substitutes for the wooden bracing by Joseph Smith in 1798; but to James Broadwood belongs the credit of trying them first above the sound-board in the treble part of the scale as long ago as 1808, and again in 1818; he did not succeed, however, in fixing them properly. The introduction of fixed resistance bars is really due to observation of Allen's compensating tubes, which were, at the same time, resisting. Sebastian and Pierre Erard seem to have been first in the field in 1823 with a complete system of roller and silk bars; but these, with a simple mode of fastening them through the sound-board to the wooden beams beneath, but, although these bars appear in their patent of 1824, which chiefly concerned their repetition action, the Erards did not either in France or England claim them as of original invention, nor is there any string-plate combined with them in their patent. James Broadwood, by his patent of 1827, claimed the combination of string-plate and resistance bars, which was clearly the completion of the wood and metal instrument, differing from Allen's in the nature of the resistance being fixed. Broadwood, however, left the brass bars out, but added a fourth bar in the middle, and the three in the treble he had previously used. It must be borne in mind that it was the trebles that gave way in the old wooden construction before the tenor and bass of the instrument. But the weight of the stringing was always increasing, and a heavy close overspinning of the bass strings had become general. The resistance bars were increased to five, six, seven, eight and, as we have seen, even nine, according to the ideas of the different English and French makers who used them in their pursuit of stability.

The next important addition to the grand piano in order of time was the harmonic bar of Pierre Erard, introduced in 1838. This was a gun-metal bar of alternate pressing and drawing power by means of screws which were tapped into the wrest-plank immediately above the treble bearings, making that part of the instrument nearly immovable; this favoured the production of higher harmonics to the treble notes, recognized in what we commonly call "ring." A similar bar, subsequently extended by Broadwood across the entire wrest-plank, was to prevent any tendency in the wrest-plank to rise, from the combined upward drawing of the strings. A method of fastening the strings on the string-plate depending upon friction, and thus dispensing with "eyes," was a contribution of the Collards, who had retained James Stewart, a man of considerable inventive power, who had been in America with Chickering. This invention was introduced in 1837. Between 1847 and 1849

¹ Pleyel exhibited a small upright piano in Paris in 1827. Pierre Erard did not turn his attention to upright pianos until 1831.
Mr Henry Fowler Broadwood, son of James, and grandson of John Broadwood, and also great-grandson of Shudi (Tschudi), invented a grand pianoforte to depend practically upon iron, in which, to avoid the conspicuous inequalities caused by the breaking of the scale with resistance bars, there should be no bar parallel to the strings except a bass bar, while another flanged resistance bar, as an entirely novel feature, crossed over the strings from the bass corner of the wrest-plank to a point upon the string-plate where the greatest accumulation of tension strain was found. Broadwood did not continue, without some compromise, this extreme renunciation of ordinary resistance means. After the Great Exhibition of 1851 he employed an ordinary straight bar in the middle of his concert grand scale, his smaller grands having frequently two such as well as the long bass bar. After 1862 he covered the wrest-plank with a thick plate of iron into which the tuning pins screw as well as into the wood beneath, thus avoiding the crushing of the wood by the constant pressure of the pin across the pull of the string, an ultimate source of danger to durability.

The introduction of iron into pianoforte structure was differently and independently effected in America, the fundamental idea there being to use a single casting for the metal plate and bars, instead of forging or casting them in separate pieces. Alpheaus Babcock was the pioneer to this kind of metal construction. He also was bitten with the compensation notion, and had cast an iron ring for a square piano in 1835, which, although not a success, gave the clue to a single casting resistance framing, successfully accomplished by Conrad Meyer, in Philadelphia, in 1833, in a square piano which still exists, and was shown in the Paris Exhibition of 1878. Meyer's idea was improved upon by Jonas Chickering (1797-1853) of Boston, who applied it to the grand piano as well as to the square, and brought the principle up to a high degree of perfection—establishing by it the independent construction of the American pianoforte.

We have now to do with over- or cross-stringing, by which the bass division of the strings is made to cross over the tenor part of the scale in a single, double or treble disposition at diverging angles—the object being in the first instance to get longer bass strings than are attainable in a parallel scale, and in the next to open out the scale and extend the area of bridge pressure on the sound-board. In the 18th century clavichords were sometimes overstrung in the lowest octave to get a clearer tone in that very indistinct part of the instrument (strings tuned an octave higher being employed). The first suggestion for the overstringing in the piano was made by the celebrated flute-player and inventor Theobald Boehm, who carried it beyond theory in London, in 1831, by employing a small firm located in Cheapside, Gerock & Wolf, to make some overstrung pianos for him. Boehm expected to gain in tone; Pape, an ingenious mechanician in Paris, tried a like experiment to gain economy in dimensions, his notion being to supply the best piano possible with the least outlay of means. Tomkinson in London continued Pape's model, but neither Boehm's nor Pape's took permanent root. The Great Exhibition of 1851 contained a grand piano, made by Lichtenhal of St Petersburg, overstrung in order to gain symmetry by two angle sides to the case. It was regarded as a curiosity only. Later, in 1855, Henry Engelhard Steinway (originally Steinweg; 1797-1871), who had emigrated from Brunswick to New York in 1840, and had established the firm of Steinway & Sons in 1853 in that city, effected the combination of an overstrung scale with the American iron frame, which exhibited in grand and square instruments shown in London in the International Exhibition of 1862, excited the attention of European pianoforte makers, leading ultimately to important results. The Chickering firm claim to have anticipated the Steinways in this invention. They assert that Jonas Chickering had begun a square piano on this combined system in 1853, but, he died before it was completed, and it was brought out later. It is often difficult to adjudicate upon the claims of inventors, so rarely is an invention the product of one man's mind alone. However, the principle was taken up and generally adopted in America and Germany, and found followers elsewhere, not only in grand but in upright pianos, to the manufacture of which it gave, and particularly in Germany, a powerful impetus.

Since 1885 the American system of a metal plate in one casting, and cross- or over-stringing by which the spun bass strings cross the longer steel diagonally, has become general in Europe with the exception of France, where musical taste has remained constant to the older wooden structure and parallel stringing throughout. The greater tenacity of the modern cast-steel wire favours a very much higher tension, and consequent easier production of the higher partials of the notes, permitting a sostenuto unknown to Beethoven, Schumann or Chopin. While in 1862 the highest tension of a concert grand piano worked out at sixteen tons, since 1885 thirty tons has been recorded. Generally speaking, the rise in tension may be expressed musically by the interval of a minor third, to the great advantage of the standing in tune. First shown by Henry Steinway in the London Exhibition of 1862, this altered construction attracted extraordinary attention at Paris in 1867, and determined the German direction of manufacture and a few years later the English. What is now particularly noticeable wherever pianos are made is the higher average of excellence attained in making, as well as in pianoplaying. Naturally the artistic quality, the personal note, characterizes all first-class instruments, and permits that liberty of choice which appertains to a true conception of art.

Much attention has been given of late years to the touch of pianos, to make it less tiring for the modern performer, especially since, in 1885-1886, Anton Rubinstein went through the herculean feat of seven consecutive historical recitals, repeated in the capital cities and principal musical centres of Europe. For even this stupendous player a light touch was indispensable. In
the competition for power piano makers had been gradually increasing the weight of touch to be overcome by the finger, until, to obtain the faintest pianissimo from middle C, at the front edge of the key, from three to four ounces was not uncommon weight. The Broadwood grand piano which Chopin used for his recitals in London and Manchester in 1848, an instrument that has never been repaired or altered, shows the resistance he required: the middle C sounds at two ounces and a half, and to that weight piano-makers have returned, regarding two ounces and three-quarters as a possible maximum. Owing to the greater substance of the hammers in the bass, the touch will always be heavier in that department, and lighter in the treble from the lesser weight. In balancing the keys, allowance has to be made for the shorter leverage of the black keys. When the player touches the keys farther back the leverage is proportionately shortened and the weight increased, and there is also an ascending scale in the weight of the player’s blow or pressure from pianissimo to fortissimo. The sum of the aggregate force expended by a pianist in a recital of an hour and a half’s duration, if calculated, would be astonishing.

The most important structural change in pianos in recent years has been the rejection of support given by metal bars or struts between the metal plate to which the strings are hitched and the wrest-plank wherein the tuning-pins are inserted. These bars formed part of William Allen’s invention, brought forward by Stodart in 1820, and were first employed for rigidity in place of compensation by the Paris Erards two years later. Broadwood in London introducing about that time the fixed metal plate. The patent No. 1231, for the barless or open-scale piano, taken out in London in 1888 by H. J. Tschudi Broadwood, is remarkable for simplification of design as well as other qualities. Ten years elapsed after the taking out of the patent before the first barless grand was heard in public (January 1868 at St James’s Hall). The metal frame, bolted in the usual manner to the bottom framing, is of fine cast steel entirely free from any transverse bars or struts, being instead turned up round the edges to form a continuous flange, which enables the frame to bear the increased modern tension while providing additional elasticity and equality of vibration power throughout the scaling. The absence of barring and bracing tends to subdue the metallic quality of tone so often observable in pianofortes constructed with heavy iron frames, and the barless steel frame being so much more elastic than the latter, no loss in resonance is perceptible. The tone of the barless grand is of singular beauty and sonority and is even throughout the compass.

The problem of resonance—with stringed keyboard instruments, the reinforcement or amplification of sound—has, from the days of the lute- and spinet-makers, been empirical. With lute, guitar, and viol or violin the sound-box comes in, combining in the instrument the distinct properties of string and enclosed air or wind. With the spinet, harpsichord and piano we have to do chiefly with the plate of elastic wood, to amplify the initial sound of the strings; and the old plan of a thin plate of spruce, put in slightly convex and with an under-barring of wood for tension, has absorbed the attention of piano-makers. The violin belly, with its bass bar and sound post, has relation to it; but the recent invention of the Stroh violin has shown that the initial string vibrations may be passed through a bridge, be concentrated, and adequately transferred to an aluminium disk not much larger than half a crown. The piano, with its numerous strings, cannot be so reduced, but the reinforcement problem is open to another solution, tentative it is true, but a possible rival. The “Gladiator” soundboard is the invention of Albert Schulz, late director of the piano manufactory of Ritmüller and Söhne of Göttingen. Dr Moser’s name has been associated with the inventor’s in the English patent. In the “Gladiator” two slabs of wood, with grain of opposed direction to give the necessary tension, are glued together, and the whole system of belly bars is done away with. There is a thinning round the edge, to facilitate promptness of speech. As we are still feeling our way towards an accurate and comprehensive statement of resonance, this invention is one claiming scientific interest, as well as being of possible practical importance.

To return to the touch. The desirability of what is called repetition—that the jack or sticker, which from the depression of the key delivers the blow that raises the hammer to the strings, should never be far away from the notch or nose which receives the impulse—is as much an object of consideration with pianomakers now as it has been since Sebastian Erard began those experiments in 1808 which ended
in his famous "double escapement" action. The principle of this grand action, like that of Wranum patented for upright pianos in 1826, has become general. But Joseph Henry Cary in 1837 (patent No. 2283) invented a simple contrivance for repetition in all pianos, neglected at the time, and subsequently repatented and disputed over by others, which has only been preserved in the records of the patent office, while the inventor has left no other mark. But the utility of the invention has come to light. It is increasingly used in the actions of upright pianos, and, in combination with the old English grand action, is successfully competing with the Erard action proper and the simplified Herz-Erard, of late years so very generally employed.

There has been a great change in the freer technique of piano-playing, partly favoured by the development of piano-making, but reacting and obliging the piano-makers to keep their attention incessantly alive to the aim and requirements of the players. It is true that the genius of Beethoven dominates a technique that has become obsolete, and so completely that the adequate performance of his piano works still gives to the sense as well as the intellect the highest pleasure, but his annotations to Cramer's Studies, as preserved by Schindler, betray the close touch of the clavichord-player and the student of C. F. E. Bach's Essay on Clavichord-Playing, as well as the weakness as a musical instrument of the early piano. The inventor of a technique so original, and at the time (c. 1839) so extraordinary, as Chopin's, sat at the piano with his elbows immovable, using, for flexility, neither wrist nor arm. With Chopin, to play loudly was anathema. The modern free style of playing comes from Czerny—whom Beethoven despised as having no legato (Bindung)—through Liszt to the Rubinsteinists and to the splendidly equipped performers of our time, to whom the pedal has become indispensable for cantabile and effect.

The most expert performers are now rivalled technically by the recent extraordinary invasion of the American automatic pianos—Erard, Pianola, Mechanik-Pianino, the Angela, Pianola, and the Erard-Clavichord, as well as the American, and other varieties of the same idea. The use of the perforated roll acts by means of the ingenious and indeed faultless application of pneumatic leverage to the ordinary piano, doing duty for the pianist's fingers; and it is made possible to play louder or softer, faster or slower, by mechanical arrangement. Such an instrument lacks the player's touch, which is as personal and indispensable for sympathy as the singer's voice or violinist's bow. Still, to a violinist, it is a benefit to have a correct coadjutor in a Beethoven or Brahms sonata with one of these handy companions, just as it is to a actor to have always at command the accompanist he or her repertory. The Apollo has the addition of a useful transposing apparatus—an aid, however, that, though often tried, has never yet been adopted; it is possibly too disturbing to the musician's ear. The mechanical tuning-pin is an analogous experiment which comes regularly under notice as the years go by, to be as persistently rejected. The most practical of these tuning inventions was the Albert, shown in the Inventions Exhibition, 1855. Here, pressure upon the strings above the wrest-plank bridge modified their tension after a first rough adjustment to pitch had been effected.

The perforated music-sheet, a mechanism common to pianoplayers, as well as self-play ing pianos, first appears in a French patent, 1842. A United States patent for a keyboard piano-player was issued to E. D. Bootman (Dec. 18, 1860), and the first pneumatic keyboard piano-player was patented in France in 1853 by M. Fourneaux. Between 1879 and 1902 a total of 55 patents had been issued in the States. The first complete automatic piano-player ready for performance was the Angeius (No. 24799, 1897). The specification is from a communication to the British patent office by Edward Hollingworth White, of Meriden, New Haven county, Conn., U.S.A. There is a pneumatic, bellows, bellows and pedals. The whole apparatus is contained in a cabinet; a bellows mounted upon camera, the pedals and operating pedal, the bellows being the actuating mechanism, a tracker adjusted for the use of a perforated music-sheet, a pneumatic motor and winding-roll mechanism to propel the music-sheet, and a series of fingers operated upon by the pneumatic mechanism, so projecting as to overhang the piano keyboard and play upon it, with rockers or levers for depressing the piano pedals. Subsequently the apparatus was made capable of detaching or detaching the tempo at the will of the operator. A roll of music, 12 in. wide and varying in length according to the composition, can be placed in position promptly, and when exhausted can be returned upon its own roll by a simple stop, and be followed by a second roll, and so on. The Clavier received its name from the use of automatic instruments by John Clavé in 1250. The Czerny was the original for the Pianola, a roll of music, 1898, the Apollo 1900. The difference of all these clever contrivances is not conspicuous to the amateur.

While these allied inventions have had to do with a substitute for touch and the necessity for the persevering acquirement of a difficult technique, another, the Virgil Practice Clavier, so called after the inventor, Mr Alon Kincaid Virgil, an American musician turned pianist and teacher of piano playing, and who intended to make it possible for anyone to acquire the technique with tone, so that the finger technique is acquired mechanically and unmusically, while value of tone, reading, expression, whatever we understand by musical production exciting our re- sponse through the ear, is delayed until the player's hand is formed and considerably developed. The opinion of some of the very greatest pianists is brought forward as approving of the system; in the work, for instance, of Vladimir de Fuchmann, they hold the Virgil technique with the Virgil-Clavier to be the only way to Europe. Bearing in mind that the minimum weight of the touch of a concert piano is not likely to exceed three and a half ounces it is hardly likely that these skilled performers use this dumb keyboard with the graduated weight advised for advancing
PIATTI (anc. Pianasio), an island of Italy, belonging to the province of Leghorn, and forming part of the commune of Marciana (Elba), from which it is 73 m. S.W. Pop. (1881), 774. As its name indicates, it is quite flat, and the highest point is only 95 ft. above sea-level. Its area is 6 sq. m. Augustus banished to it his grandson, Agrippa Postumus, and some ruins of baths near the harbour still bear his name. It changed hands more than once in the wars between Pisa and Genoa in the 11th and 13th centuries; from 1390 it belonged to the prince of Piombino, but was depopulated in 1555 by the Turkish fleet, and only resettled at the beginning of the 19th century. In 1857 a penal colony was established here.

PIÀRISTS, the popular name of a Catholic educational order, the "clerici regulares scholorum piorum," the Pauline Congregation of the Mother of God, founded by Joseph Calasanza (Josephus a Matre Dei) at Rome in the beginning of the 17th century. Calasanza, a native of Calasanza in the province of Huesca in Aragon, was born on September 11, 1556, studied at Lerida and Akald, and after his ordination to the priesthood removed to Rome (1592). Here he organized, in 1607, a brotherhood which ultimately, in 1617, became an independent Congregation, numbering at that time fifteen priests, under Calasanza as their head. To the three usual vows they added a fourth, that of separation to the gratuitous instruction of youth. In 1622 the Congregation received a new constitution from Gregory XV., and had all the privileges of the mendicant orders conferred upon it, Calasanza being recognized as general. In 1643 the jealousy of the Jesuits led to his removal from office; owing to the same cause the Congregation was deprived of its privileges by Innocent X. in 1646. Calasanza, who died on August 22, 1648, was beatified in 1748, and canonized in 1767. The privileges of the Congregation were successively restored in 1660, 1669 and 1668. The Piarists, who are not numerous, are found chiefly in Italy, Spain, the West Indies, Germany, and especially in Austria-Hungary. Before the course of study authorized by the state, a Piarist establishment contained nine classes: reading, writing, elementary mathematics, schola parva or Rudimentorum, schola Principiorum, Grammatica, Syntaxis, Humanitas or Poesis, Rhetorica. The general provost of the order is chosen by the general chapter, and with a general procurator and four assistants resides at Rome. The members are divided into professors, novices, and lay brethren. Their dress is very similar to that of the Jesuits; their motto "Ad majus pietatis incrementum!"

half of each series. His purely classical style, his wide musical sympathies, and his general culture and charm, would have ensured him a high position even without his marvellously finished technical skill. In 1804 the fiftieth anniversary of his first appearance in London was celebrated by a reception given in honour of him and his lifelong friend Joachim. He retired from public life, owing to a severe illness, in 1807, and until his death at Bergamo on the 15th of July 1801 divided his time between his native town and Cadenzabba. As a composer he attained a wide popularity with some graceful and popular songs; he did excellent work as an editor; and he was an enthusiastic collector and musical antiquary.

PIAÚHY, or PIAUHY, a north-eastern state of Brazil, bounded N. and W. by Maranhão, E. by Minas Gerais, Paranámbuco and Bahia, and S. by Bahia. It has a few miles of Atlantic coast-line on the N., and the Rio Parnaíba forms the boundary line with Maranhão throughout its entire length. Area, 116,523 sq. m.; pop. (1900), 334,428. Part of the state on the Atlantic coast and along the lower Parnaíba is low, swampy and malarial. South of this the country rises gradually to a high plateau with open campos. This plateau region is watered by numerous tributaries of the Parnaíba, chief of which are the Urussuhy, the Canindé and its tributary the Piauí, the Gurugua and its tributary the Parahim, which drains the large inland lake of Parnaquá, the Longa, and the Poty, which has its source in the state of Ceará. The Parnaíba is navigable for boats of 3 ft. draught up to Nova York, a few miles above the mouth of the Gurugua, and could be made navigable up to the mouth of the Balsas. The climate is hot and humid in the lowlands and along the lower Parnaíba, but in the uplands it is dry with high sun temperatures and cool nights. The principal industry is stock-raising, which dates from the first settlement in 1674 by Domingos Afonso Malfrense, who established here a large number of cattle ranges. A secondary industry is the raising of goats, which are able to stand neglect and a scanty food supply. Sheep have likewise been raised in Piauí, but there is no market for mutton and their wool is not utilized. The agricultural products are: cotton, sugar and tobacco. Of food-stuffs the people do not produce enough for their own consumption. Forest products include rubber, carnauba wax and dyewoods. The exports include hides, skins, rubber, wax, tobacco and cotton. The capital is Therezina, on the right bank of the Parnaíba, 250 m. above Parnaíba (town), with which it is connected by a line of light-draught river boats. The town dates from 1852, is attractively situated, and is regularly laid out with broad, straight streets crossing each other at right angles. The population of the município in 1890 was 31,553, which includes a large rural district. Other towns, with their populations in 1890, are São José dos Cedros (9,133), Fortaleza de Cachoeira (9,216), Amarante (15,252); Valença (17,650); and Campo Maior (12,425), the figures given of population being those of the large districts (municípios) in which the towns are situated.

PIAZZA, properly an open square or place in an Italian town (Ital. piazza, from Lat. platea, broad space, Gr. πάροσ, broad). These squares were usually surrounded with a colonnade or arcade, and thus the word has been loosely applied to a covered walk or arcade along the front of a building, and in America, to the veranda of a house.

PIAZZA ARMERINA, a city of Sicily, in the province of Caltanissetta, 39 m. by road E.S.E. from that town, and the same distance S. of the railway station of Assoro-Vulcanarne, 43 m. W. of Catania, situated 2360 ft. above sea-level. Pop. (1901), 24,119. It has a 15th-century cathedral, with a fine campanile, and some of the houses show Norman or Gothic architecture. The foundation of the town dates from the 11th century, and the dialect is Lombard.

See Macerdi in L'Arte (1906), 14.

PIAZZI, GIUSEPPE (1746-1826), Italian astronomer, was born at Ponte, in the Valtellina, on the 10th of July 1746. He entered the Theatine Order in 1764, accepted the chair of mathematics in the academy of Palermo in 1780, and persuaded the viceroy, Prince Caramanico, to build an observatory there.

During a visit to England in 1798 he procured from Jesse Ramsden a five-foot altazimuth, with which he collected at Palermo, 3792-1813, the materials for two admirable star-catalogues, published in 1805 and 1814 respectively. While engaged on this work he discovered, on the 1st of January 1801, the first asteroid or minor planet, to which he gave the name of Ceres, the tutelary deity of Sicily. He died at Naples on the 22nd of July 1826.

See B. E. Mainieri, L'Astronomo Giuseppe Piazzi (Milan, 1871); Palafox, 3792-1813, the materials for two admirable star-catalogues, published in 1805 and 1814 respectively. While engaged on this work he discovered, on the 1st of January 1801, the first asteroid or minor planet, to which he gave the name of Ceres, the tutelary deity of Sicily. He died at Naples on the 22nd of July 1826.

PIBRA, GUY DE FAUR, SEIGNEUR DE (1690-1758), French jurist and poet, was born at Toulouse, of an old family of the magistracy. He studied law there with Jacques Cujas, and afterwards at Padua. In 1752 he was admitted to the bar at Toulouse, at once took high rank, and rose to be juge-magist, an office in Languedocian cities about equal to that of prêtre.

He was selected in 1752 as one of the three representatives of the king of France at the council of Trent. In 1750 he became general advocate to the parlement of Paris, and extended the renaissance in jurisprudence which was transforming French justice. In 1753 he was sent by Charles IX. to accompany as commissioner his brother Henry (afterwards Henry III.) to Poland, of which country Henry had been elected king. Although autofranc Latin won much applause from the Poles, but his second visit to Poland in 1757, when sent back by Henry III. to try to save the Crown he had deserted, was not so successful. Then he was employed in negotiations with the so-called politiques, and he managed to keep them quiet for a while. In 1758 he became the chancellor of Marguerite of France, queen of Navarre. Although he was fifty, her beauty and intellectual gifts led him to aspire to win her affection; but he was rejected with disdain. He died in 1758. His oratorical style was too pedantic, but quotations from the classics had a fresher meaning in his day. He was the friend of Ronsard, de Thou and L'Hôpital, and, left among other literary remains, elegant and sententious quadratines.

PIBROCH, a form of music as played by the bagpipe. The word is derived from the Gaelic piobaireacht, the art of the bagpiper. This special form of bagpipe music, consisting of a series of variations founded on a theme, was called the sirlar. These variations are generally of a martial or warlike character and include dirges and marches (see BAGPIPE).

PICA, the name of the European representative of a group of diminutive rodent mammals, also known as tailless hares, mouse-hares, or piping hares, constituting the family Ochotonidae with the single genus Ochotona. From the more typical hares and rabbits they are distinguished in form, ears, and rabbits they are distinguished in form, ears, the absence of a tail, and the relatively shorter hind-limbs, as well as by complete collar-bones. The soles of the feet are hairy, and the fur is usually soft and thick; while in some cases the last upper molar is absent. Picas are inhabitants of cold and desert regions. They dwell either in the chimneys between rocks, or in burrows, although one Himalayan species frequents pine-forests. They are very active, and most of the species utter a piping or whistling cry. They store up a supply of grass for winter use; in Siberia it is stocked in small heaps. The Himalayan Ochotona roylei may be seen in the daytime, but most kinds are nocturnal. The Siberian species, O. altaica, ranges into eastern Europe, but Central Asia is the headquarters, although a few species range into Arctic America and the Rocky Mountains. In size picas may be compared to guinea-pigs. Till of late years the group has been generally known by the name of Lagomys. There are several distinct genera.

(R. L.)

PICA, the Latin name of a genus of oscine passerine birds, the magpies. The Latin word, by interchange of initial p and l, is possibly the Gr. σλασσα (see MAGPIE), and probably the same word as picus, the woodpecker (q.v.). Another derivation would connect both pica and picus with the root pie- of pingere, to
paint, from the parti-coloured appearance of the bird. It is this “pied” or black and white look of the page that probably gave the name of *pica*, “pie” or “type” to the ordinary printed in black and white. It is therefore a size of type in printing coming next to “English” (see Typography). The Gr. κιςσα and Lat. *pica* were used of a perverted craving for unnatural foods; and the word has been adopted in this sense in modern medical terminology.

**Pica**

**Pica**

**Picard,** Louis Joseph Ernest (1821–1877), French politician, was born in Paris on the 24th of December 1821. After taking his doctorate in law in 1840 he joined the Parisian bar. Elected to the corps législatif in 1858, he joined the group of Émile Ollivier. But as Ollivier approximated to the government standpoint, Picard, one of the members of the group known as Les Cing, veered more to the left. He founded in 1860 a weekly democratic journal, *L’Électeur libre*, and in 1869 was elected both for Hénin and Paris, electing to sit for the former. From the 4th of September 1870 he held the portfolio of finance in the government of National Defence. In January 1871 he accompanied Jules Favre to Versailles to arrange the capitulation of Paris, and in the next month he became minister of the interior in Thiers’s cabinet. Attacked both by the Monarchist and the Republican press, he resigned in May. Later in the year he was sent as ambassador to Brussels, where he remained for two years. On his return to Paris he resumed his seat in the Left centre, and in 1875 became life senator. He died in Paris on the 13th of May 1876.

**Picardie** (La Picardie), one of the old provinces of France, bounded on the N. by Hainaut and Artois, on the E. by Champagne, on the S. by the Île de France, and on the W. by Normandy and the English Channel. Its maritime frontier ran from the mouth of the Aa to the cliffs of Caux, and it included the whole of the basin of the Somme and part of that of the Oise. The chief towns of Picardy were Amiens, Boulogne, Abbeville, Laon, Soissons, Montreuil, Péronne, Beauvais, Montdidier, St Quentin and Noyon. Its principal rivers were the Somme and the Oise. Picardy formed part of the archdiocese of Reims, and its bishoprics were Amiens, Beauvais, Senlis, Soissons, Noyon and Laon. In 1789 the province of Picardy was covered by the three bishoprics of Amiens, Noyon and Boulogne. It was one of the provinces of the five great fermes, districts subject to the tariff of 1664, and in judicial matters was under the authority of the parlement of Paris. Its area now forms the department of the Somme and parts of the departments of Pas de Calais, Aisne and Oise.

The name of Picardy does not appear until the 13th century, but was employed by Matthew Paris and was in general use in the 14th century. In the 13th century the province was divided into the two bailliages of Amiens and Vermandois, but its regular organization as part of the kingdom of France only dates from the beginning of the 16th century. At this time it was divided into north and south Picardy. North Picardy, or Picardy proper, formed one of the great military governorships of the kingdom, while south Picardy was included in the Île de France. North Picardy was divided into upper and lower Picardy, the former being the interior part of the province and the latter the district along the coast. Upper Picardy comprised the districts of Amiénois, Santerre, Vermandois and Thiérache, and lower Picardy those of Ponthieu, Vinieu, Boulonnais and Calaisis, or the Pays reconquis; south Picardy included the districts of Beauvaisis, Laonnois and Soissonsais.

Under the Romans Picardy was part of Belgica secunda; it was inhabited by the Morini, the Ambiani, the Veromandui, the Bellovaci and the Butissois, whose names still haunt Amiens, Vermandois, Beauvais and Soissons. The Romans intersected the district with roads and built several castra to defend the valley of the Somme. In the 3rd century Christianity was preached here, and St Quentin and others were martyred. A little later abbots were founded, among them Corbie, St Valéry and St Riquier. Early in the 5th century Picardy became the centre of Merovingian France, for, as the historian Michelet says, “Thistoire de l’antique France semble entassée en Picardie.” Clovis had his first capital at Soissons. Charlemagne had his at Noyon, and Laon was the capital and the refuge of the later and feebler Carolingian sovereigns.

During the later feudal period Picardy was the home of the counts of Vermandois, of Clermont and of Ponthieu, the sire of Coucy and others. The neighbouring dukes of Burgundy cast covetous eyes upon the province; in 1435, by the famous treaty of Arras, the royal towns and lands in the valley of the Somme were ceded by King Charles VII to Burgundy. However, after the death of Charles the Bold in 1477 Picardy was finally united with the crown of France. The province was early an industrial district. Flemish immigrants brought with them the lucrative trade of weaving cloth, and the Somme towns were soon competing with those of Flanders. The Picard towns were settled for their love of independence, which often brought them into collision with the kings of France during the 13th century. At a later time the province received a number of Spanish immigrants. In the middle ages the Picards formed one of the four “nations” at the university of Paris. Picardy has a high place as a home of Gothic art, this being testified to by the superb cathedrals at Amiens and Noyon, while within its borders is the famous château of Coucy.

Picardy has a literature of its own, which was rich and popular in the 12th century. It suffered greatly from the ravages of the Normans, and later during the Hundred Years’ War and the wars between France and Spain. Within it are the famous fields of Picardy. The Picard had a high reputation as a soldier, being sometimes called the “Gascon of the North,” and in 1538 Henry II. created the *régiment de Picardie*. Many anthropological remains have been found in the Somme valley.

**Picarese**

**Picarese**

**Picarese Novel, The.** This special form of the roman noir structures may be defined as the prose autobiography of a real or fictitious personage who describes his experiences as a social parasite, and who satirizes the society which he has exploited. The picaroon, or rogue type, is represented by Encolpos, Ascytios and Giton in the Satyricon which tradition ascribes to Petronius; it persists in Lucian, in the *Roman de Renart*, in the *fableux*, and in other works popular during the middle ages; and it is incarnated in real life by such men of genius as the Archpriest of Hita and François Villon. But in its final form the picarese novel may be regarded as a Spanish invention. The word *pícaro* is first used, apparently, in a letter written by Eugenio de Salazar at Toledo on the 17th of April 1560; the etymology which derives *pícaro* from *picar* (to pick up) is unsatisfactory to philologists, but it suggests the picaroon’s chief business in life. In the *Tesoro de la lengua castellana* (Madrid, 1611) Sebastián Covarrubias y Orozco, the best of Spanish lexicographers, describes a *pícaro* as a man of loose character engaged in menial work and—by extension—a rascal who attains his ends by skilful dissimulation; and the earliest application of the expression *pícaro* to a character in fiction occurs in Mateo Aleman’s *Guzmán de Alfarache*, the first part of which was published in 1590. But a genuine *novela picaresca* existed in Spain before the word *pícaro* became generally current.

The earliest specimen of the kind is *La Vida de Lazarillo de Tormes y de sus fortunas y adversidades*, an anonymous tale attributed to Insufficient grounds, Diego Hurtado de Mendoza (g.v.). The authorship of this, the earliest of its publication are obscure; however, it was certainly issued not later than 1554, and was thrice reprinted before 1559, when it was placed on the Index. Imitations of so successful a story were inevitable, and so early as 1555 there appeared at Antwerp *La Segunda parte de Lazarillo de Tormes*, an anonymous sequel which completely misinterpreted the irreverent wit of the original. The first part had been prohibited because of its attacks on the
clergy; in the second part the hero is presented as a devout youth transformed into a tunny at the intercession of the Virgin Mary, who thus saved him from death; after many extravagant experiences in this form he is restored to human shape, and proposes to teach the submarine language at the university of Salamanca. This dull performance naturally failed to please and, meanwhile, many surreptitious copies of the first part were introduced into Spain; the Inquisition finally gave up the attempt to suppress it, and in 1597 an unexpurgated edition was authorized. With this mutilated version the Spanish public was for a time content during the remaining fifteen years of Philip II.'s reign. Upon the death of this sombre monarch society relaxed its hypocractic pose of austerity, and in 1599 Mateo Aleman (q.v.) published the *Primer parte de Guzmán de Alfarache*. It is modelled upon *Lazarillo de Tormes*, being the autobiography of the son of a ruined Genoese money-lender; but the writer indulges in a tedious series of moralizings. This contrasts sharply with the laconic cynicism of *Lazarillo de Tormes*; but *Guzmán de Alfarache* is richer in invention, in variety of episode and in the presentation of character. Its extraordinary popularity tempted a Valencian lawyer named Juan José Martí to publish a *Segunda parte de la vida del picaro Guzmán de Alfarache* (1612) which is a sequel of the *Primer parte* of Mateo Luján de Sayavedra. Though partly plagiarized from the manuscript of the genuine second part to which Martí had somehow obtained access, the continuation was coldly received; in 1604 Aleman brought out the true continuation, and revenged himself by introducing into the narrative a brother of Martí—a crazy picaroon of the lowest morality who ultimately commits suicide in disgust at his own turpitude. In *Lazarillo de Tormes*, and still more in *Guzmán de Alfarache*, it is difficult to distinguish between the invented episodes and the personal reminiscences of the authors. The *Viage entretenido* (1605) of Agustín de Rojas is a realistic account of the writer's experiences as a strolling actor and playwright, and, apart from its considerable literary merits, it is an invaluable contribution to the history of the Spanish stage as well as a graphic record of contemporary low life; the chief character in the book is called el caballero del milagro, an expression which recurs in Spanish literature as the equivalent of a chevalier d'industrie.

The next in chronological order of the Spanish picarosque tales is *La Picara Justina* (1605), the history of a woman picaroon, which has long been customary to ascribe to Andrés Pérez, a Dominican monk; there is, however, no good reason to suppose that the name of Francisco Lópe de Ubeda on the title-page is a pseudonym. *La Picara Justina* is a realistic account of the writer's experiences as a strolling actor and playwright, and, apart from its considerable literary merits, it is an invaluable contribution to the history of the Spanish stage as well as a graphic record of contemporary low life; the chief character in the book is called el caballero del milagro, an expression which recurs in Spanish literature as the equivalent of a chevalier d'industrie.

*XXI. 19*
broke all the Commandments, how he found himself stranded in Madrid, how his fine air captivated Lope de Vega, who housed him for eight months and dedicated to him a play entitled Rey sin reino, and how the ex-captain ended by "resolving to retire to a lonely spot and there serve God as a hermit." Every convention of the picaresque novel is faithfully observed, and the incidents are no doubt substantially true, though Contreras, like most converts, judges his own past with unnecessary harshness. This subtle form of vanity also pervades the Comentarios de él descuido de sí mismo of Diego de Estrada, a rakish soldier and inferior dramatist whose autobiography (begun in 1614 and continued at intervals during many years) was not printed till 1680. A far higher order of talent distinguishes the Capitulaciones de la vida de la corte y oficios entenidos in ella, a bitterly unsparring review of picaresque life written by the great satirist Francisco Gomez de Quevedo y Villegas (q.e.). These thumbnail sketches were the preparatory studies worked up into the more elaborate Vida del buscon Don Palkos (1626), the cleverest and most revolting book of its class. There is no attempt to scare the wicked by means of awful examples; the moral lesson is contemptuously thrown to be; the veil of romance is rent by truth, and the picaro—the nephew of the public executioner—is revealed as he is, gloating in cruelty and reveling in the conscious enjoyment of crime. But though Quevedo detests mankind, his morose vision of existence rarely degenerates into caricature. In his repugnant, misanthropic masterpiece the sordid genius of the Spanish picaro finds absolute expression. Nothing further remained to be done in the matter of realism; henceforth the taste for picaresque novels grew less keen, and later writers unconsciously began to humanize their personages.

The Varia fortuna del soldado Piniedo (1628) added nothing to the established reputation of Gonzalo Clapides and Meneses. A clever anonymous story, Don Rainuado el entretenido (1627), missed fire, even though it was attributed to Quevedo; yet the author, Diego Tovar y Valderrama, compiled a sprightly diary of the events which make up a picaro's crowded day, and failed solely because the interest in rogues was waning. Other writers of undoubted gifts were slow to see that the fashion had changed. Alonso de Castro Solórzano (q.e.) tempted the public with three picaresque stories published in quick succession: La Nita de los embistes, Teresa de Mananzaren (1634), the Aventuras del Bachiller Trapez (1637) and a sequel to the latter entitled La Garduilla de Sevilla (1642). Clever as Castro Solórzano's stories are, their titles would have been meaningless in the absence of an enthusiasm in Spain; the Bachiller Trapez was destined to be continued by Mateo da Silva Cabral in Portugal and to be exploited by Le Sage in France, and to these two accidents it owes its survival. Le Sage likewise utilized in Gil Blas episodes taken from El Siglo picaro (1644), the work of Antonio Enriqández Gómez (q.v.); but most of El Siglo picaro is in verse, and as it was published at Paris by an exiled Portuguese Jew, its circulation in Spain must have been limited. The normal picaresque rogue returns to the scene in La Vida y hechos de Estebanillo Gonzales (1646), which is no doubt the genuine autobiography that it purports to be. If he is still occasionally read by students he owes it to the fact that Le Sage's Historie d'Estevanillo Gonzales. By the general public he is completely forgotten, and the same may be said of many subsequent Spanish writers who adopted the picaresque formula. The Buscon is the last great book of its kind.

Meanwhile, the rogue had forced his way into other European literatures. The Antwerp continuation (1555) of Lazarillo de Tormes brought the original to the notice of northern readers, and this first part was translated into French by Jean Saugrini in 1561. A Dutch version was issued anonymously in 1579, and it seems extremely likely that the book had been translated into English by this time. This follows from a manuscript note written by Gabriel Harvey in a copy of this Heautoglass given him by Edmund Spenser; Harvey here mentions that he had received the Heautoglass, Skoggon, Skelton and Lazarillo from Spenser on the 20th of December 1578. The earliest known edition of David Rowland's version of Lazarillo de Tormes is dated 1586, but as a licence to print a translation of this tale was granted on the 22nd of July 1568/1569, it is probable that a 1576 edition which appears in the Harleian Catalogue really existed. Numerous reprints (1599, 1639, 1660-1670, 1672, 1677) go to prove that Lazarillo de Tormes was very popular, and that Shakespeare had read it seems to follow from an allusion in Much Ado about Nothing (Act. i. sc. 1): "Now you strike like the blind man; that was the way that I lay you out, and you will beat the post." To Thomas Nash belongs the credit, such as it is, of being the first to write a picaresque novel in English: The Unfortuniate Traveller; or the Life of Jack-Wilson (1594). Nash carefully points out that his work is a new experiment, "being a cleane different veine from other my former courses of writing"; the only possible Spanish model that he can have had was Lazarillo de Tormes, but he has nothing of his predecessor's sardonic brevity, and he anticipates later Spanish writers by his emphatic insistence on the pleasures of eating and drinking to repletion. Nash led the way, and a reference to "Spanish pickaroes" in Middleton's Spanish Gipsie indicates that the picaro type had speedily become familiar enough for London playwrights to understand the reference. Interest in picaresque literature was kept alive in England by a translation (1622) of a sequel to Lazarillo de Tormes published at Paris two years earlier by Juan de Luna, who came to London to supervise the English rendering; by James Mabbe's admirable version (1622) of Gueomán de Alfarrache; by The Son of the Rogue or the Politic Thief (1638), an anonymous translation, done through the French, of La desordenada codicia; and by another anonymous translation (1657), likewise done through the French, of Quevedo's Buscon. The result of this campaign was The English Rogue described in the Life of Meriton Latroon, a witty Extravagant (1665), by Richard Head and Francis Kirkman. The authors of this farrago insist on the English nationality of their chief character, and repudiate the idea that they are in any way indebted to Alemán and Quevedo. It is no exaggeration, however, to say that almost all the material in the text is taken from Spanish sources, and even the thieves' vocabulary is stolen from John Awdley's Fraternitie of Vagabondes or Thomas Harman's Caveat, or Warning for Common Cursetors. It is not till Defoe's time that the English picaresque novel acquires any real importance, and the picaresque intention informs much of his work that contravenes the accepted rules of composition. There is a female picaro in Moll Flanders, and, as Defoe read Spanish, it is conceivable that Moll Flanders was suggested by the Picaresca Justina; but this resemblance does not make Moll Flanders a real model of Moll Flanders. The satirical spirit which is lacking in Moll Flanders is abundantly present in Colonel Jack, which bravely aims at exhibiting "vice and all kinds of wickedness attended with misery." Henceforward the picaro is naturalized in English literature, and is gloriously reincarnated in Fielding's Jonathan Wild and in Smollett's Ferdinand, Count Fathom. The classification of Sterne's Tristram Shandy and Morier's Haji Bobje as picaresque novels is not strictly accurate; like Pickwick and Oliver Twist and Barry Lyndon, they are rather varieties of the pietapetic novel, but many incidents in all five reveal a convincing liking with the Spanish picarescos.

The Dutch translation of Lazarillo de Tormes (1579) did not enable the picaresque novel to strike root in Holland, yet from it is derived one of the best Dutch comedies, De Spanische Brabander Jorolino (1616) of Gerbrand Bredero. A German translation of Guemnán de Alfarrache was published by Aegidius Albernus in 1615; both Lazarillo and Rinconete y Cortadillo were translated by Niclas Ulenhart in 1716, and in 1627 there appeared an anonymous version of the Picaresca Justina. The Spanish tradition was followed by Martin Frewen a continuation (1626) of Guemán de Alfarrache, but the original picaresque novel of real value in German is Grimmelhausen's Der Sturm. The attempt to aclimatize the picaresque novel in Italy failed completely.
development. The same may be said of Portugal; for though
Silva Cabrál's continuation of the Bachiller Travesa is called
the most remarkable of Portuguese picarese romances, it is
significant that O pereirillo de Cordova remains in manuscript.

The case was very different in France, where pictures of low
life had always found admirers. The first translation of Las-
riño de Tormes appeared, as already noted, at Paris in 1561; the
first translation of the first part of Guzmán de阿尔法科 was
issued there by Gabriel Chappuis in 1600, and the dictator
Chaplain designed to translate both parts in 1610-1620; the first
translation of the Novelas ejemplares was published at Paris in
1618 by Rosset and d'Audiguier; and French translations of
Marco de Obregón, of La Desordenada codicia, of the Buseón and
of the Picara Justina were printed in 1618, 1621, 1633 and 1635
respectively. Before this series of translations was completed
Charles Sorel recounted in Franclon (1622) "the comic mishaps
whichbefall evil-doers," invoking the common excuse that it is
"lawful to find pleasure at their expense." Many of the
episodes in Franclon are picarese in tone, but unfortunately
Sorel wanders from his subject, and devotes no small part of his
book to satirizing literary men who, though tribbles or paupers,
and would be picaroons. The legitimate Spanish tradition is
followed more closely and with more ability by Paul
Scarron in the Roman comique (1651), in which horseplay is
predominant. The framework may have been suggested by
Agustín de Rojas or Quevedo, both of whom introduce a strolling
company, and such characters as Llandre, Angélique de l'Etoile
and Ragotin might be found in any average novea picaresca.

Scarron frankly mentions Castillo Solórzano's Garduña de Sevilla
in his text, and his Prentacion inutil and Les Hypocrates are
convincing proofs of close study of Spanish picarese stories;
The Prentacion inutil is taken from Guzmán de阿尔法科, and
Les Hypocrates is merely a translation of Salas Barbadillo's
Hija de Celestina. The Roman bourgeois (1666) of Antoine
Furetière is generally described as a picarese novel, but this
involves a new definition of the adjective; the Roman bourgeois
includes some portraits and more satire which seem suggested
by picarese reading, but it is concerned with the foibles of the
middle class rather than with the sly devices of common
vagabonds.

The Spanish picaroon lives again in Gil Blas, where, with a
dexterity almost rarer than original genius, a master of literary
manipulation fuses materials unearthened from forgotten and
seemingly worthless Spanish tales of the 16th century. Gil Blas is a creation of
the gentler, sunnier French spirit; like Beaumarchais' Figaro he is
a Spanish born, reared and humanized in Paris, and these
two are the only picarons whose relative refinement has not
been gained at the cost of verisimilitude. But the old original
scoundrel was not yet extinct: in the interval between the appear-
nance of the Barbier de Steille and the Mariage de Figaro Resti-
de la Bretonne produced a sequel (1776) to the Buseón—a sequel
so dull as to be wellnigh unreadable. The untamed Spanish
rogue had become impossible towards the end of the 18th cen-
tury: in the 19th he was deliberately rejected when Théophile
Gautier wrote his Capitaine Fracasse. Yet Gautier conscienti-
ously provides a Spanish atmosphere for his personages, with
Spanish names, and uses Spanish inscription; the host
speak Spanish, as well as with a Spanish accent; Valombreuse parts from
the marquis with a Spanish formula: "beso á vuestra merced
la mano, caballero." Capitaine Fracasse is the last important
book which continues the picarese tradition. The possibilities
of picarese fiction can never be exhausted while human nature
is unchanged. Pereda (q.v.) in Pedro Sánchez (1854) touches
the old theme with the accent of modernity. It may be that
instead of one continuous tale, interrupted by episodical
digressions, the picarese fiction of the future will take the form
of short stories independent of one another; but this would be
nothing more than a convenient mechanical device, a readjust-
ment of means to ends.

PICAYUNE—PICCINNI

PICAYUNE, the name in Florida and Louisiana of a small Spanish
half-real, 1/16 of a dollar, 63 cents, and hence used of the United
States 5 cent piece. The French pièces d'argile, from which the word
was adapted in America, was an old copper coin of Piedmont.
Its origin is doubtful, but is possibly related to the Italian piccolo,
little, small. In America the word is used of anything trifling,
pretty, mean or contemptible.

PICCANINY, or Piccaninny, a word applied originally by
the negroes of the West Indies to their babies. It is adapted
either from Span. pequeño, small, or Port. pequenino, very small.
The word spread with the slave trade to America, and has since
been adopted in Australia and in South Africa.

PICCININO, NICCOLO (1386-1444), Italian condottiere, born at
Perugia, was the son of Pero Piccinino. He began his military career
in the service of Braccio da Montone, who at that time was
waging war against Perugia on his own account, and at the death
of his chief, shortly followed by that of the latter's son Oddo,
Piccinino became leader of Braccio's condotta. After serving
for a short period under the Florentine Republic, he went over to
Filippo Maria Visconti, duke of Milan (1425), in whose service
with Nicolò Fortebraccio he fought in the wars against
the league of Pope Eugenius IV, Venice and Florence. He defeated
the papal forces at Castel Bolognese (1434), but another
papal army under Francesco Sforza having defeated and killed
Fortebraccio at Firdi恐龙e, Piccinino was left in sole command,
and in a series of campaigns against Sforza he seized a number
of cities in Romagna by treachery. In 1439 he again fought in
Lombardy with varying success against Sforza, who had now
entered the Venetian service. Piccinino then induced the duke
of Milan to send him to Umbria, where he hoped, like so many
other condottieri, to carve out a dominion for himself. He
was defeated by Sforza at Anghiari (1440), but although a number of
his men were taken prisoners they were at once liberated, as
was usually done in wars waged by soldiers of fortune. Again
the war shifted to Lombardy, and Piccinino, having defeated
and surrounded Sforza at Martinengo, demanded of the visconti
the lordship of Piacenza at the price of Sforza's capture. The
latter, however, firmly rejected the proposal and concluded a truce with Sforza; but the
latter, who, while professing to defend the Papal States, had
established his own power in the Marche, aroused the fears
of the pope and the king of Naples, as well as of the visconti, who
gave the command of their joint forces to Piccinino.
Sforza was driven from the Marche, but defeated Piccinino at Monte-
lauro, and while the latter was preparing for a desperate effort
against Sforza he was suddenly recalled to Milan, his army was
beaten in his absence, and he died of grief and of his wounds in
1444. Short of stature, lame and in weak health, he was brave
to the point of foolhardiness, wonderfully resourceful, and never
overwhelmed by defeat; but he was cruel and treacherous, and
had a thirst for power beyond his own aggrandizement. Piccinino left two
sons, Jacopo and Francesco, both distinguished condottieri.

A good account of Piccinino is contained in vol. iii. of E. Riccotti's
Storia della compagnia di ventura (Turin, 1845); G. B. Poglio, Vita
di N. Piccinino (Venice, 1572); see also the general histories of
the period.

PICCININI, NICCOLO (1725-1800), Italian musical composer,
was born at Bari on the 16th of January 1728. He was
educated under Leo and Durante, at the Conservatorio
di Sant' Onofrio in Naples. For this Piccinini had to thank
the intervention of the Bishop of Bari, his father, although
himself a musician being opposed to his son's following a
musical career. His first opera, Le Donne dispettose,
was produced in 1755, and in 1760 he composed at Rome,
the chief d'œuvre of his early life, La Cecchina, ossia la buona
PICCOLO—PICCOLOMINI, O.

Piccinia, an opera buffa which attained a European success. Six years after this Piccinia was invited by Queen Marie Antoinette to Paris. He had married in 1756 his pupil Vincenza Sibilla, a singer, whom he never allowed after her marriage to appear on the stage. All his next works were successful; but, unhappily, the directors of the Grand Opéra conceived the mad idea of deliberately opposing him to Gluck, by persuading the two composers to treat the same subject—Iphigénie en Tauride—simultaneously. The Parisian public now divided itself into two rival parties, which, under the names of Gluckists and Piccinists, carried on an unruly and disgraceful war. Gluck's masterly Iphigénie was first produced on the 18th of May 1779. Piccinini's Iphigénie followed on the 23rd of January 1781, and, though performed seventeen times, was afterwards consigned to oblivion. The fury of the rival parties continued unabated, even after Gluck's departure from Paris in 1780; and an attempt was afterwards made to inaugurate a new rivalry with Sacchini. Still, Piccinni held a good position, and on the death of Gluck, in 1787, proposed that a public monument should be erected to his memory—a suggestion which the Gluckists themselves declined to support. In 1784 Piccinni was professor at the Royal School of Music, one of the institutions from which the Conservatoire was formed in 1794. On the breaking out of the Revolution in 1789 Piccinni returned to Naples, where he was at first well received by King Ferdinand IV.; but the marriage of his daughter to a French democrat brought him into irretrievable disgrace. For nine years after this he maintained a precarious existence in Venice, Naples and Rome; but he returned in 1798 to Paris, where the fickle public received him with enthusiasm, but left him to starve. He died at Passy, near Paris, on the 7th of May 1800. After his death a memorial tablet was set up in the house in which he was born at Bari.

The very complete list of his works is that given in the Rivista musicale italiana, viii. 75. He produced over eighty operas, but although his later work shows the influence of the French and German stage, he belongs to the conventional Italian school of the 18th century.

See also P. L. Giuguen6, Notice sui la vie et les ouvrages de Niccolo Piccinni (Paris, 1801); E. Demaille, La Musique française au 18e siècle Gluck et Piccini 1770-1800 (1872).

PICCOLO (Fr. petite flûte octave; Ger. Pichelflöte; Ital. flauto piccolo or ottavino), a small flute of less than half the dimensions of the large concert flute and pitched an octave higher. The principles of construction and the acoustic properties are the same for the piccolo as for the flute, with the exception that the piccolo does not contain the additional tail-piece with the extra low keys, which give the flute its extended compass. As the pitch of the piccolo is so high, the highest of all orchestral instruments with the exception of a few harmonics on the violin, the music for it is written an octave lower than the real sounds in order to avoid the ledger lines. The piccolo has been used with good effect in imitating the whistling of the wind in storms, as in Beethoven's Pastoral Symphony, Wagner's Flying Dutchman, and in conjunction with the violins in tremolo to depict the rustling of the leaves in the breeze, as in the "Waldverein" in Siegfried. Verdi employed it to advantage in Falstaff as a comic agent in humorous situations. The piccolo is generally in D, sometimes in E or F.

PICCOLOMINI, the name of an Italian noble family, which was prominent in Siena (q.v.) from the beginning of the 13th century onwards. In 1220 Enghelberto d’Ugo Piccolomini received the fief of Montetarti in Val d'Orcia from the emperor Frederick II. as a reward for services rendered. The family acquired houses and towers in Siena and castles in the republic's territory, including Montone and Castiglione; the latter they sold to the commune in 1211. They obtained great wealth through trade, and established counting-houses in Siena, Venice, Aquila, Trieste, and in various cities of France and Germany. Supporters of the Guelf cause in the civil broils by which Siena was torn, they were driven from the city in the time of Manfred and their houses demolished; they returned in triumph after the Angelvin victories, were expelled once more during the brief reign of Conradin, and again returned to Siena with the help of Charles of Anjou. But through their riotous political activity the Piccolominis lost their commercial influence, which passed into the hands of the Florentines, although they retained their palaces, castles and about twenty fiefs, some of which were in the territory of Arezzo. Many members of the family were distinguished ecclesiastics, generally placed in Siena and elsewhere; two of them were popes, viz. Aeneas Silvius Piccolomini (Pius II., q.v.) and Francesco Piccolomini (Pius III., q.v.).

See Richter, Die Piccolominis (Berlin, 1874); A. Lisini and A. Liberati, Albero della famiglia Piccolomini (Siena, 1899); and articles by A. Lisini in the Miscellanea storica senese, 3rd series 12, and 4th series, 17 and 189.

PICCOLOMINI, OCTAVIO, PRINCE (1599-1659), duke of Amalfi, Austrian general, was born on the 11th of November 1599 in Florence, and carried a pike in the Spanish service at the age of sixteen. Two years later, on the outbreak of the Thirty Years' War in Bohemia, he was appointed a captain in a cavalry regiment sent by the grand duke of Tuscany to the emperor's army, and he fought with some distinction under Buquoy at the Weisser Berg and in Hungary. In 1624 he served for a short time in the Spanish army and then as lieutenant-colonel of Pappenheim's cuirassier regiment in the war in the Milanese. In 1627 he re-entered the Imperial service as colonel and captain of the lifeguard of Wallenstein, duke of Friedland. In this capacity he soon fell into disgrace for practising extortion at Stargard in Pomerania, but his adroitness secured him, after no long interval, the rank of "colonel of horse and foot." About this time the appointment of his younger brother to the archbishopric of Siena secured him a position of influence in the diplomatic world. Diplomatic talent was indeed almost the birthright of a member of an Italian family, that had seen two of its members occupying the papal chair, and Wallenstein freely made use of his subordinate's capacity for negotiation and intrigue. In the events of the Mantuan War Piccolomini took a prominent part in the dual rôle of the subtle diplomatist and the plundering soldier of fortune. At this moment came the invasion of Germany by Gustavus Adolphus. Piccolomini was interned at Ferrara as a hostage for the ratification of a treaty, but he added his voice to the general call for Wallenstein's reappointment to the imperial command in the Netherlands. He was not, however, included in the list of promotions that followed the duke's reappearance, and he served under General Holk, an officer brought in from the Danish service, in the preliminary operations and in the battle of Lützen. His ambition was gratified when, on reading the official report of the battle, the emperor made him a generalfeldwachtmeister. At the same time, however, Holk was created a field marshal at Wallenstein's instance, much to his rival's chagrin. In the campaign of 1633 Piccolomini held the command of an important detachment posted at Königgrätz to bar the enemy's advance from Silesia into Bohemia. History repeated itself on the same ground in 1756, 1778 and 1866; in the first of these cases it was a Piccolomini, grand-nephew of Octavio, who commanded the Austrians; in the last the victorious Prussians passed over the estate of Nachod, which after 1635 was a hereditary possession of the family. In May Wallenstein entered Silesia with the main army with the unwavoured object of compelling or persuading the electors of Brandenburg and Saxony to make common cause with the emperor against the Swedes. Piccolomini was with him, and, disapproving of the duke's policy, joined in a military conspiracy, out of which grew the drama that ended with the murder of Wallenstein on the 25th of February 1634. Piccolomini's own part in the tragedy has been set forth for all time in the pages of Schiller's Wallenstein. He was the duke's baton, 100,000 gulden and the beautiful estate of Nachod in the Kleinseite.

He was Wallenstein's pupil as well as his sayer, and had learned the art of war from that master. On the 5th-6th of September in the same year he distinguished himself amongst the foremost in the great victory of Nördlingen. He soon saw the necessity for following out the lines of military policy laid
down by the duke, but neither he nor Gallus, the new lieutenant-general of the emperor, possessed the capacity for carrying it out, and the war dragged on year after year. Piccolomini was in 1635 allied with a Spanish army, and bitterly complained that their sloth and caution marred every scheme that he formed. In 1638 he was made a count of the empire, and in 1639, having been a fortnight too late, was forced to win a great victory over the French (relief of Thionville, July 7, 1639), he was rewarded with the office of privy councillor from the emperor and with the dukedom of Amalfi from the king of Spain. But instead of being appointed, as he hoped, Gallas’s successor, he was called in to act as ad latus to the Archduke Leopold Wilhelm, with whom he was defeated in the second battle of Breitenfeld in 1642. After this he spent some years in the Spanish service and received as his reward the title of grandee and the order of the Golden Fleece. Some years later, having re-entered the Imperial army, he was again disappointed of the chief command by the selection of the brave veteran Peter Melander, Count Holzapfel. But when in 1648 Melander fell in battle at Zunzamhausen, Piccolomini was at last appointed lieutenant-general of the emperor, and thus conducted as generalissimo the final campaign of the weary and desultory Thirty Years’ War. Three days after the commission for executing the peace had finished its labours, the emperor addressed a letter of thanks, “to the Prince Piccolomini,” and awarded him a gift of 114,566 gulden. Piccolomini died on the 11th of August 1656. He left no children (his only son Joseph Silvio, the “Max” of Schiller’s Wallenstein, was murdered by the Swedes after the battle of Jankau in 1654), and his titles and estates passed to his brother’s son. With the death of the latter’s nephew Octavio Aeneas Josef in 1757, the line became extinct.

**PICENE.** C₂H₅NO, a hydrocarbon found in the pitchy residue obtained in the distillation of peat-tar and of petroleum. This is distilled to dryness and the distillate repeatedly recrystallized from cymene. It may be synthetically prepared by the action of anhydrous aluminium chloride on a mixture of naphthalene and ethylene dibromide (R. Lespieau, *Bull. soc. chim.*, 1891, 3, 6, p. 238), or by distilling a-dinaphthosulfone (T. Hirn, *Ber.*, 1899, 32, p. 3341). It crystallizes in large colourless plates which possess a blue fluorescence. It is soluble in concentrated sulphuric acid with a green colour. Chromic acid in glacial acetic acid solution oxidizes it to picene-quinoine, picene-quinoic acid, and sulphuric acid solution and phosphoric acid to form hydriodic acid and phosphorus it forms hydrides of composition C₂H₄NO and C₂H₅NO (see E. Bamberger and F. D. Chattaway, *Ann.*, 1895, 284, p. 61).

**PICENUM,** a district of ancient Italy, situated between the Apenines and the Adriatic, bounded N. by the Senones and S. by the Vestini. The inhabitants were, according to tradition, an offshoot of the Sabines. Strabo (v. 4, 1) gives the story of their migration, led by a woodpecker (*picus*), a bird sacred to Mars, from which they derived their name Picentini (cf. Dion. Hal. i. 14, §1). It was just the Hirpini derived theirs from *hirpus*, a wolf. The district was conquered by the Romans early in the 3rd century B.C. and the whole territory was divided up among Latin-speaking settlers by the Lex Flaminius in 232 B.C. Hence we have very scanty records of any non-Latin Language that may have been spoken in the district before the 3rd century. Besides the problematic inscriptions from Belmonte, Nereto and Cupra Marittima (see Sabellic), we have one or two Latin inscriptions (probably of the 6th or even the 1st century B.C.) which contain certain forms showing a distinct affinity with the dialect of Iguvium (cf. the name *Paddi*=Latin *Pocidii*). Hence there seems some ground for believing that the population which the Romans dispossessed, or held in subjection, really spoke a dialect very much like that of their neighbours in Umbria.

For inscriptions, see R. S. Conway, *The Italic Dialects*, p. 499. For the place-names and personal names of the district, see also found; see further, Livy, *Ept.* xxv.; B. V. Head, *Historia numorum*, p. 19. (R. S. C.)

It was in Picenum, at Asculum, that the Social War broke out in 90 B.C. At the end of the war the district became connected with Pompeii Strabo, and his son Pompey the Great threw into the scale on the side of Sulla, in 83 B.C., all the influence he possessed there, and hoped to make it a base against Caesar’s legions in 49 B.C. Under Augustus it formed the fifth region of Italy, and included twenty-three independent communities, of which five, Ancona, Firmum, Asculum, Hadria and Interamnia, were *coloniae*. It was reached from Rome by the Via Salaria, and its branch the Via Caecilia. It was also on a branch leading from the Via Flaminia at Nucceria Camellaria to Sep_CODEC_temple. There were also communications from north to south; a road led from Asculum to Urbs Salvia and Ancona, another from Asculum and Firmum and the coast, another from Urbs Salvia to Potentia, while finally along the whole line of the coast there ran a prolongation of the Via Flaminia, the name of which is not known to us.

At the end of the 2nd century A.D. the north-eastern portion of Umbria was divided from the rest and acquired the name Flaminia, from the high road. For the time it remained united with Umbria for administrative purposes, but passed to Picenum at latest in the time of Constantine, and acquired the name of *Flaminia* or *Picenum Annonarium*, the main portion of Picenum being distinguished as *Suburbanium*. In an inscription of A.D. 309 Ravenna is actually spoken of as the chief town of Picenum. When the exarchate of Ravena was founded the part of Picenum Annonarium near the sea became the *Pentapolis Maritima*, which included the five cities of Ariminum, Pisaurum, Fanum Fortunae, Sena Gallica and Ancona. The exarchate was seized by Luitprand in 727, and Ravena itself was taken by Alstulf in 752. In the next year, however, the emperor Pippin took it from him and handed it over to the pope, a grant confirmed by his son Charlemagne. (T. A.S.)

**PICHIGRUS, CHARLES** (1761-1864). French general, was born at Arbois, or, according to Charles Nodier, at Les Planches, near Lons-le-Saulnier, on the 16th of February 1761. His father was a labourer, but the friars of Arbois gave the boy a good education, and one of his masters, the Père Partault, took him to the military school of Brienne. In 1783 he entered the first regiment of artillery, where he rapidly rose to the rank of adjutant-sub-lieutenant. When the Revolution began he became leader of the Jacobin party in Besançon, and when a regiment of volunteers of the Gard marched through the city he was elected lieutenant-colonel. The fine condition of his health, and his robust disposition, and a stream of victory over the Rhine, and his organizing ability was made use of by an appointment on the staff, and finally by his promotion to the rank of general of brigade. In 1793 Carnot and Saint Just were sent to find roturier generals who could be successful; Carnot discovered Jourdan, and Saint Just discovered Hoche and Pichigrus. In co-operation with Hoche and the army of the Moselle, Pichigrus, now general of division and in command of the army of the Rhine, had to reconquer Alsace and to reorganize the disheartened troops of the republic. They succeeded; Pichigrus made use of the *clan* of his soldiers to win innumerable small engagements, and with Hoche forced the lines of Haguenau and relieved Landau. In December 1793 Hoche was arrested, it is said owing in part to his colleague’s machinations, and Pichigrus became commander-in-chief of the army of the Rhine-and-Moselle, whence he was summoned to succeed Jourdan in the army of the North in February 1794. It was now that he fought his three great campaigns of one year. The English and Austrians held a strong position along the Sambre to the sea. After vainly attempting to break the Austrian centre, Pichigrus suddenly turned their left, and defeated Clerfayt at Cassel, Menin and Courtrai, while Moreau, his second in command, defeated Coburg at Tourcoing in May 1794; then after a pause, during which Pichigrus feigned to besiege Ypres, he again dashed at Clerfayt and defeated him at Rousselle and Hooglede, while Jourdan came up with the new army of the Sambre-and-Meuse, and utterly routed the Austrians at Fleaurus on the 27th of June 1794. Pichigrus began his second campaign by crossing the Meuse on the 18th of October, and after taking Nijmegen drove the Austrians beyond the Rhine. Then, instead of going into winter-quarters, he prepared his army for a winter
campaign. On the 28th of December he crossed the Meuse on the ice, and stormed the island of Bommel, then crossed the Waal in the same manner, and, driving the English before him, entered Utrecht on the 19th of January, and Amsterdam on the 20th of January, and soon occupied the whole of Holland. This grand feat of arms was marked by many points of interest, such as the capture of the Dutch ships, which were frozen in the Hedel, by the French hussars, and the splendid discipline of the ragged battalions in Amsterdam, who, with the richest city of the continent to sack, yet behaved with a self-restraint which few revolutionary and Napoleonic armies attained. The former friend of Saint Just now offered his services to the Thermidorians, and after receiving from the Convention the title of "Sauveur de la Patrie," subdued the sans-culottes of Paris, when they rose in insurrection against the Convention on 12 Germinal (April 1). Pichegru then took command of the armies of the North, the Sambre-and-Meuse, and the Rhine, and crossing the Rhine in force took Mannheim in May 1795. When his fame was at its height he allowed his colleague Jourdan to be beaten, betrayed all his plans to the enemy, and took part in organizing a conspiracy for the return of Louis XVIII, in which he was to play, for his own aggrandizement, the part that Monk played from higher motives in the English revolution. His intrigues were suspected, and when he offered his resignation to the Directory in October 1795 it was to his surprise promptly accepted. He retired in disgrace, but hoped to serve the royalist cause by securing his election to the Council of Five Hundred in May 1797. He was there the royalist leader, and planned a coup d'état, but on the 18th Fructidor he was arrested, and with fourteen others deported to Cayenne in 1797. Escaping, he reached London in 1798, and served on General Korsakov's staff in the campaign of 1799. He went to Paris in August 1803 with Georges Cadoudal to head a royalist rising against Napoleon; but, betrayed by a friend, he was arrested on the 28th of February 1804, and on the 15th of April was found strangled in prison. It has often been asserted that he was murdered by the orders of Napoleon, but there is no foundation for the story.

Pichegru's campaigns of 1794 are marked by traits of an audacious genius which would not have disgraced Napoleon. His tremendous physical strength, the personal command he gained by this and by his powers of command made him a peculiarly formidable opponent, and thus enabled him to maintain a discipline which guaranteed the punctual and perfect execution of operations. He had another peculiar advantage of captivating honest men like Moreau. He flattered in turn Saint Just and the Thermocrats, the Thermidors and the Directors, and played always for his own hand—a strange egotist who rose to fame as the leader of an idealist and sentimental crusade.

There is no really good life of Pichegru; perhaps the best is J. M. Gassier's Vie du général Pichegru (Paris, 1815). For his treason, trial and death, consult Montgillard's Mémories concernant la trahison de Pichegru (1804); Fauche-Borel's Mémoires du savant, Mémories sur la mort de Pichegru (Paris, 1829); and G. Pierrot, Pichegru, son procès et sa mort (1826).

PICHLER, CAROLINE (1769-1843). Austrian novelist, was born at Vienna on the 7th of September 1769, the daughter of Hofrat Franz von Greiner, and married, in 1796, Andreas Pichler, a government official. For many years her salon was the centre of the literary life in the Austrian capital, where she died on the 9th of July 1843. Her early works, Olivier, first published anonymously (1802), Idyllen (1803) and Ruth (1805), though displaying considerable talent, were immature. She made her mark in historical romance, and the first of her novels of this class, Agatha (1808), an answer to Gibbon's attack on that historian in the Decline and Fall of the Roman Empire, attained great popularity. Among her other novels may be mentioned Die Belagerung Wiens (1824); Die Schwestern in Prag (1827); Die Wiedererobung Oefens (1829) and Henriette von England (1832). Her last work was Zeitbilder (1840).

The edition of Karoline Pichler's Sämtliche Werke (1829-1845) comprises no less than 60 volumes. Her Denkwürdigkeiten aus meinem Leben (4 vols.) was published posthumously in 1844. A selection of her narratives, Ausgewählte Erzählungen, appeared in 4 vols. in 1854.

PICKENS, ANDREW (1739-1817), American soldier in the War of Independence, was born in Paxton, Bucks county, Pennsylvania, on the 19th of September 1739. His family settled at the Waxhaws (as is now Lancaster county), South Carolina, in 1752. He fought against the Cherokees in 1761 as a lieutenant. In the War of Independence he rose to brigadier-general (after Cowpens) in the South Carolina militia. He was a captain among the American troops which surrendered at Ninety Six in November 1777. On the 14th of February 1779, with 300-400 men, he surprised and defeated about 700 Loyalists under Colonel Boyd on Kettle Creek, Wilkes county, Georgia; on the 20th of June he fought at Stono Ferry; and later in the same year at Tomasee defeated the Cherokees, who were allied with the British. Upon the surrender of Charleston (May 1780) he became a prisoner on parole, which he observed rigidly until, contrary to the promises made to him, Major James Dunlap plundered his plantation; he then returned to active service. His command (about 150 men) joined General Daniel Morgan immediately before the battle of Cowpens, in which Pickens commanded an advance guard (270-350 men from Georgia and North Carolina) and twice rallied the broken American militia; for his services Congress gave him a sword. With Colonel Henry Lee he harassed Lieut.-Colonel Banastre Tarleton, who was attempting to gather a Loyalist force just before the battle of Guilford Court House; and with Lee and others, he captured Augusta (June 5, 1781) after a siege. At Eutaw Springs (Sept. 8, 1781) he commanded the left wing and was wounded. In 1782 he defeated the Cherokees again and forced them to surrender all lands south of the Savannah and east of the Chattahoochee. After the war he was a member of the South Carolina House of Representatives for a number of years, of the state Constitutional Convention in 1790, and of the National House of Representatives in 1793-1795. He died in Pendleton district, South Carolina, on the 17th of August 1817. He had married in 1765 Rebecca Calhoun, an aunt of John C. Calhoun. Their son, ANDREW PICKENS (1779-1838), served as a lieutenant-colonel in the War of 1812, and was governor of South Carolina in 1816-1818.

PICKENS, FRANCIS WILKINSON (1803-1858), American politician, was born in Togado, St. Paul's parish, South Carolina, on the 12th of April 1805, son of Andrew Pickens (1779-1852) and grandson of General Andrew Pickens (1733-1817). He was educated at Franklin College, Athens, Georgia, and at South Carolina College, Columbia, and was admitted to the bar in 1829. In 1832 he was elected to the state House of Representatives, where, as chairman of a sub-committee, he submitted a report denying the right of Congress to exercise any control over the states. He was a Democratic member of the National House of Representatives in 1833-1843, served in the South Carolina Senate in 1844-1845, was a delegate to the Nashville Southern Convention (see Nashville, Tennessee) in 1839, was United States minister to Russia in 1858-1860, and in 1860-1862 was governor of South Carolina. He strongly advocated the secession of the Southern states; signed the South Carolina ordinance of secession; protested against Major Robert Anderson's removal from Fort Moultrie to Fort Sumter; sanctioned the firing upon the "Star of the West" (Jan. 9, 1861), which was bringing supplies to Anderson, and the bombardment of Fort Sumter; and was a zealous supporter of the Confederate cause. At the close of his term he retired to his home at Edgefield, South Carolina, where he died on the 25th of January 1869.

PICKERING, EDWARD CHARLES (1846- ), American physicist and astronomer, was born in Boston on the 19th of July 1846. He graduated in 1865 at the Lawrence Scientific School, Harvard, where he was for the next two years a teacher of mathematics. Subsequently he became professor of physics at the Massachusetts Institute of Technology, and in 1876 he was appointed professor of astronomy and director of the Harvard College observatory. In 1877 he decided to
devote one of the telescopes of the observatory to stellar photometry, and after an exhaustive trial of various forms of photometers, he devised the meridian photometer (see Photometry, Stellar), which seemed to be free from most of the sources of error. With the first instrument of this kind, having objectives of 1.5 inch aperture, he measured about 400 stars, including all stars down to the 6th magnitude between the North Pole and -30° declination. With the object of reaching fainter stars, Professor Pickering constructed another instrument of larger dimensions, and with this more than a million observations have been made. The first important work undertaken with it was a revision of the magnitudes given in the Bonn Durchmusterung. On the completion of this, Professor Pickering decided to undertake the survey of the southern hemisphere. An expedition, under the direction of Prof. S. I. Bailey, was accordingly despatched (1880), and the meridian photometer erected successively in three different positions on the slopes of the Andes. The third of these was Arequipa, at which a permanent branch of the Harvard Observatory is now located. The magnitudes of nearly 8000 southern stars were determined, including 1428 stars of the 6th magnitude and brighter. The instrument was then returned to Cambridge (U.S.A.), where the survey extended so as to include all stars of magnitude 7.5 down to -90° declination, after which it was once more sent back to Arequipa. In 1886 the widow of Henry Draper, one of the pioneers of stellar spectroscopy, made a liberal provision for carrying on spectroscopic investigations at Harvard College in memory of her husband. With Professor Pickering's usual comprehensiveness, the inquiry was so arranged as to cover the whole sky; and with four telescopes—two at Cambridge for the northern hemisphere, and two at Arequipa in Peru for the southern—to which a fine 24-in. photographic telescope was afterwards added, no fewer than 75,000 photographs had been obtained up to the beginning of 1901. These investigations have yielded many important discoveries, not only of new stars, and of large numbers of variable stars, but also of a wholly new class of double stars whose binary character is only revealed by peculiarities in their spectra. The important conclusion has been already derived that the majority of the stars in the Milky Way belong to one special type.

Pickering, Timothy (1745-1829), American politician, was born in Salem, Massachusetts, on the 17th of July 1745. He graduated from Harvard College in 1763 and was admitted to the bar in 1768. In the pre-revolutionary controversies he identified himself with the American Whigs; in 1773 he prepared for Salem a paper entitled State of the Rights of the Colonists; in 1775 he drafted a memorial protesting against the Boston Port Bill; and in 1776 he was a representative from Salem in the General Court of Massachusetts. In 1766 he had been commissioned lieutenant and in 1756 captain in the Essex county militia; early in 1773 he published An Easy Plan of Discipline for a Militia, adopted in May 1776 by the General Court for use by the militia of Massachusetts, and he was elected colonel of his regiment. In the same year he became judge of the court of common pleas for Essex county, and sole judge of the maritime court for the counties of Suffolk, Essex, and Middlesex. In the winter of 1776-1777 he led an Essex regiment of volunteers to New York, and he subsequently served as adjutant-general (June 1777-Jan. 1778) and later as quartermaster-general (1780-1785); he was also a member of the board of war from the 7th of November 1777 until its abolition. With the aid of some officers he drew up, in April 1783, a plan for the settlement of the North-West territory, which provided for the exclusion of slavery. In 1785 he became a commission merchant in Philadelphia; but in October 1786, soon after the legislature of Pennsylvania had passed a bill disfranchising the Whig district into the county of Lazene, he was appointed prothonotary and a judge of the court of common pleas and clerk of the court of sessions and orphans' court for the new county, and was commissioned to organize the county. He offered to purchase for himself the Connecticut title to a farm, and in the following year he was appointed a member of a commission to settle claims according to the terms of an act, of which he was the author, confirming the Connecticut titles (see Wyoming Valley and Wilkes-Barre). Pickering was a member of the Pennsylvania convention of 1778 which ratified the Federal constitution, and of the Pennsylvania constitutional convention of 1789-1790. In December 1790 he negotiated a peace with the Seneca Indians, and he concluded treaties with the Six Nations on the 1791, in March 1792 and in November 1794. Under Washington he was postmaster-general (1791-1795), secretary of war (1795), and after December 1795 secretary of state, to which position he was reappointed (1797) by Adams. In 1783, while he was quartermaster-general, he had presented a plan for a military academy at West Point, and now, as secretary of war, he supervised the West Point military post with a view to its conversion into a military academy. As head of the state department he soon came into conflict with Adams. His hatred of France made it impossible for him to sympathize with the president's efforts to settle the differences with that country on a peaceable basis. He used all his influence to hamper the president and to advance the political interests of Alexander Hamilton, until he was dismissed, after refusing to resign, in May 1800. Returning to Massachusetts, he served as chief justice of the court of common pleas of Essex county in 1802-1803. He was a United States senator in 1803-1811 and a member of the Federal House of Representatives in 1813-1817. As an ultra Federalist—he was a prominent member of the group known as the Essex Junto—he strongly opposed the purchase of Louisiana and the War of 1812. He died at Salem, Massachusetts, on the 29th of January 1829.

The standard biography is that by his son, Octavius Pickering (1791-1868), and C. W. Upham, The Life of Timothy Pickering (4 vols., Boston, 1867-1873). In the library of the Massachusetts Historical Society at Boston, there are sixty-two manuscript volumes of the Pickering papers, an index to which was published in the Collections of the society, 6th series, vol. viii. (Boston, 1890).

His son, John Pickering (1777-1846), graduated at Harvard in 1796, studied law and was private secretary to William Smith, United States minister to Portugal, in 1797-1799, and to Rufus King, minister to Great Britain, in 1799-1801. He practised law in Salem and (after 1827) in Boston, where he was city solicitor in 1827-1846, and wrote much on law and especially on the languages of the North-American Indians. He was a founder of the American Oriental Society and published an excellent Comprehensive Dictionary of the Greek Language (1826).

See Mary O. Pickering (his daughter), Life of John Pickering (Boston, 1887).

Timothy Pickering's grandson, Charles Pickering (1805-1878), graduated at Harvard College in 1823 and at the Harvard Medical School in 1826, practised medicine in Philadelphia, was naturalist to the Wilkes exploring expedition of 1838-1842, and in 1843-1845 travelled in East Africa and India. He wrote The Races of Man and their Geographical Distribution (1848), Geographical Distribution of Animals and Man (1854), Geographical Distribution of Plants (1861) and Chronological History of Plants (1879).

Pickering, a market town in the Whity parliamentary division of the North Riding of Yorkshire, England, 32 m. N.E. by N. from York by the North Eastern railway, the junction of several branch lines. Pop. of urban district (1901), 3,491. The church of St Peter is Norman and transitional Norman, with later additions including a Decorated spire. It contains a remarkable series of mural paintings of the 15th century. The castle, on a hill to the north, is a picturesque ruin, the fragmentary keep and several towers remaining. The work is in part Norman, but the principal portions are of the 14th century. One of the towers is connected in name and story with Fair Rosamond. The castle was held by Earl Morcar shortly before the Conquest; it then came into the hands of the Crown, and subsequently passed to the duchy of Lancaster. It was the prison of Richard II. before his confinement at Pontefract. During the civil wars of the 17th century the castle was held by the Royalists, and suffered greatly in siege. The district
surrounding Pickering is agricultural, and the town is a centre of the trade. Agricultural implements are manufactured, and limestone and freestone are quarried in the vicinity.

**PICKET.** Pique or Picquet (Fr. *pique*, a pointed stake or peg, from *piquer*, to point or pierce), a military term, signifying an outpost or guard, supposed to have been introduced into the army about 1660, from the resemblance that an infantry company on outpost duty dispersed its musketeers to watch, the small group of pikemen called *pique* remaining in reserve. Thus at the present day the word “*pique*” is, in Great Britain at any rate, restricted to an infantry post on the outpost line, from which the sentries or “groups” of watchers are sent out. In the United States a “*picket*” is synonymous with a sentry, and the “picket-line” is the extreme advanced line of observation of an army. In the French army picquets are called “grand’ gardes,” and the phrase “grand guard” is often met with in English military works of the 17th and 18th centuries. A body of soldiers held in readiness for military or police duties within the limits of a camp or barracks is also called a picquet or “lining picquet.” These special uses of the word in English are apparently quite modern (after about 1750). “*Picket*” in its ordinary meaning of a peg or stake, has always been in common military use, being applied variously to the picketing pegs in horse-lines, to long pointed stakes employed in palisades or stockades, to straight thin rods used for marking out the line of fire for guns, &c. Of the various spellings “*picquet*” is officially adopted in Great Britain and “*picket*” in the United States, but the latter is now invariably used when a peg or stake is meant.

Two obsolete meanings of the word should also be mentioned. The “picket” was a form of military punishment in vogue in the 16th and 17th centuries, which consisted in the offender being forced to stand on the narrow flat top of a peg for a period of time. The punishment died out in the 18th century and was so far unfamiliar by 1800 that Sir Thomas Picton, who ordered a mulatto woman to be so punished, was accused by public opinion in England of inflicting a torture akin to impalement. It was thought, in fact, that the prisoner was forced to stand on the head of a pointed stake, and this error is repeated in the *New English Dictionary*. In the middle of the 19th century, when elongated rifle bullets were a novelty, they were often, and especially in America, called picquets. The ordinary military use of the word gives rise to compound forms such as “picket boat” or “picket launch,” large steam launch or pinnace fitted with guns and torpedoes, and employed for watching the waters of harbours, &c. For picketing in strikes, &c., see below.

**PICKETING,** a term used to describe a practice resorted to by workmen engaged in trade disputes, of placing one or more men near the works of the employer with whom the dispute is pending, with the object of drawing off his hands or acquiring information useful for the purposes of the dispute. In England, under the Conspiracy and Protection of Property Act 1875, it is an offence wrongfully and without legal authority to watch or beset the house or place where another resides or works, or carries on business or happens to be, or the approach to such house or place, if the object of the watching, &c., is to compel the person watched, &c., to abstain from doing or to do an act which he is legally entitled to do or to abstain from doing (§ 7). The definition of the offence was qualified by a proviso excluding from punishment those who attend at or near a house or place merely to obtain or communicate information, in other words what is termed peaceful picketing, without intimidation, molestation or direct efforts to influence the course of a trade dispute. This distinction led to a great deal of litigation between trade unions and employers; and trade unions were in some instances restrained by injunction from picketing the works of employers. The decisions of the courts upon this subject met with severe criticism from the leaders of trade unions, and by the Trades Disputes Act 1906 the proviso above quoted was repealed, and it was declared lawful for one or more persons acting for themselves or for a trade union or for an individual employer to attend at or near a house, &c., “if the attendance is merely for the purpose of peacefully obtaining or communicating information or of peacefully persuading any person to work or abstain from working. The exact effect of this change in the law has not yet been determined by the courts, but during the Belfast carters’ strike of 1907 serious trouble occurred in which the authorities attempted to counteract the interference with lawful business by free use of picketing. The change in the law is supplemented by provisions forbidding actions against trade unions in respect of any tortious acts alleged to have been committed by or on behalf of the union.

**PICKLE.** In the wider sense the term “pickle” is applied to any saline or acid preservative solution; in the narrower to vegetables preserved in vinegar. The word appears to be an adaptation of Dutch *pekel*, brine, pickle; cf. Ger. *Pököl*. The ultimate origin is unknown; connexions with a supposed inventor’s name, such as *Bewsker* or *Blicked* are mere inventions. A solution of copper or zinc sulphate is used as a “pickle” for railway-sleeper or other wood, a brine containing salt and saltpetre as a preservative for meat, lime-water as “pickle” for eggs. Domestic pickles are made from small cucumbers, onions, cauliflower, cabbages, mangoes and unripe walnuts, by either steeping or boiling them in salt-brine and vinegar. On account of the large proportion of water natural to these vegetables, only the strongest vinegar, containing from 5 to 6% of acetic acid, can be used. For the better kinds vinegar made from malted or unmalted barley is as a rule employed, for cheaper varieties simply dilute acetic acid obtained from acetate of lime. Sauces such as Worcestershire sauce, or Yorkshire relish, consist of fluid pickles, that is of salted and variously spiced vinegar solutions or emulsions containing tissue of vegetables (tomatoes, mushrooms, &c.), or of fish (sardines or anchovies).

**PICKNELL, WILLIAM LAMB** (1854–1897), American landscape-painter, was born at Hinesburg, Vermont, on the 23rd of October 1854. He was a pupil of George Inness in Rome for two years, and of J. L. Gérôme in the École des Beaux Arts, Paris. With Robert Wylie he worked for several years in Brittany, at Pont Aven and Concarneau, where he painted his “Route de Concarneau” (Corcoran Art Gallery, Washington, D.C.). His “Morning on the Loing” received a gold medal at the Paris Salon of 1895. In 1880 he became a member of the Society of American Artists, and in 1891 an associate of the National Academy of Design. He died at Marblehead, Massachusetts, on the 8th of August 1897.

**PICNIC,** a term of entertainment in which the guests are invited to join an excursion to some place where a meal can be taken in the open air. During the first half of the 19th century the essential of a picnic was that the guests should each bring with them a contribution of provisions. At the beginning of the 19th century a society was formed in London called the “Picnic Society,” the members of which supped at the Pantheon in Oxford Street, and drew lots as to what part of the meal each should supply (see Beaux of the Regency, 1906, i. 222). The French form *pique-rique* is said to be of recent introduction in 1692 (Ménage, Dict. etym.). It is doubtful whether picnic is merely a rhyming word, or can be referred to *pique*, pick, and *rique*, small coin.

**PICO,** an island in the Atlantic Ocean, belonging to Portugal, and forming part of the Azores archipelago. Pop. (1909), 24,028; area 175 sq. m. Pico is a conical mountain, rising to the height of 7612 ft. The soil consists entirely of pulverized lava. The so-called Fayal vineyard, though named after an adjacent island, was formerly produced here, and largely exported to Europe. But in 1852 the vines were attacked by the *Oidium* fungus and completely destroyed, while the orange-trees suffered almost as much from the *Coccus hesperidum*. The people were consequently forced to emigrate in great numbers, till the planting of fig-trees and apricots alleviated the evil. Pico also produces a species of wood resembling mahogany, and equal in quality to it. Its chief town is Lagens do Pico. Pop. (1907), 24,028.

**PICO DELLA MIRANDOLA, GIOVANNI,** COUNCIL (1463–1494), Italian philosopher and writer, the youngest son of Giovann...
PICRIC ACID—PICRITE

Francesco Pico, prince of Mirandola, a small territory about 30 Italian miles west of Ferrara, afterwards absorbed in the duchy of Modena, was born on the 24th of February 1463. The family was illustrious and wealthy, and claimed descent from Constanzo. In his fourteenth year Pico went to Bologna, where he studied for two years, and was employed with the Decretals. The traditional studies of the place, however, disgusted him; and he spent seven years wandering through all the schools of Italy and France and collecting a precious library. Besides Greek and Latin he knew Hebrew, Chaldee and Arabic; and his Hebrew teachers (Elia del Medigo, Leo Abarbanel and Jochanan Aleman—see L. Geiger Johanns Reuchlin (1871), p. 167) introduced him to the Kabbalah, which had great fascinations for one who loved all mystic and theosophical speculation. His learned wanderings ended (1486) at Rome, where he set forth for public disputation a list of nine hundred questions and conclusions in all branches of philosophy and theology. He remained a year in Rome, but the disputation he proposed was never held. The pope prohibited the little book in which they were contained, and Pico had to defend the impugned theses (De omni re scibili) in an elaborate Apologia. His personal orthodoxy was, however, subsequently vindicated by a brief of Alexander VI., dated 15th June 1493. The suspected theses included such points as the following: that Christ descended ad inferos not in His real presence but quoad effectum; that no image or cross should receive latria even in the sense allowed by Thomas; that it is more reasonable to regard Origen as saved than as damned; that it is not in a man's free will to believe or disbelieve an article of faith as he pleases. But perhaps the most startling thesis was that no science gives sure conviction of the divinity of Christ than "magia" (i.e. the knowledge of the secrets of the heavenly bodies) and Kabbalah. Pico was the first to seek in the Kabbalah a proof of the Christian mysteries and it was by him that Reuchlin was led into the same delusive path.

Pico had been up to this time a gay Italian nobleman; he was tall, handsome, fair-complexioned, with keen grey eyes and yellow hair, and a great favourite with women. But his troubles led him to more serious thoughts; and he published, in his 28th year, the Hetpeplus, a mystical exposition of his views. Next he planned a great seven-fold work against the enemies of the Church, of which only the section directed against astrology was completed. After leaving Rome he again lived a wandering life, often visiting Florence, to which he was drawn by his friends Politian and Marsillius Ficinus, and where also he came under the influence of Savonarola. It was at Florence that he died on the 17th of November 1494. Three years before his death he parted with his share of the ancestral principality, and designed, when certain literary plans were completed, to give away all he had and wander barefoot through the world preaching Christ. But these plans were cut short by a fever which carried him off just at the time when Charles VIII. was at Florence.

Pico's works cannot now be read with much interest, but the man himself is still interesting, partly from his influence on Reuchlin and partly from the spectacle of a truly devout mind in the brilliant circle of half-pagan scholars of the Florentine renaissance.

His works were published at Bologna in 1496 by his nephew, Giov. Fran. Pico, with a biography, which was translated by Sir Thomas More as Life of John Pico, Earl of Mirandola. See the essay in Walter Pater's Renaissance (1878); and the study by J. Rigg prefixed to the reprint of More's Life in the "Tudor Library" (London, 1890).

PICRIC ACID, or TRINITROPHENOL, C6H3-NO2, [1:2:4-6], an explosive and dyestuff formed by the action of concentrated nitric acid on indigo, aniline, resins, silk, wool, leather, &c. It is the final product of the direct nitration of phenol, and is usually prepared by the nitration of the mixture of phenol sulphones obtained by heating phenol with concentrated sulphuric acid (E. Eisenmann and A. Arche, Engl. pat., 4539 (1888)). It may also be obtained by oxidizing the symmetrical trinitrobenzene with potassium ferrocyanide in alkaline solution (P. Hepp, Ann. 1882, 215, p. 352). It crystallizes from water in yellow plates melting at 122°-2°C, which sublime on careful heating, but explode when rapidly heated. It is poisonous and possesses a bitter taste, hence its name from the Greek μάκαρος, bitter. It has a strongly irritating reaction, being almost comparable with the carbonate and bicarbonate of potassium. By the action of bleaching powder it is converted into chloropicrin, CCl3N2O2. Phosphorus pentachloride converts it into picryl chloride, C6H3Cl(NO2)2, which is a true acid chloride, being decomposed by water with the regeneration of picric acid and the formation of hydrochloric acid; with ammonia it yields picramide, C6H4 NH2NO2. Silver picrate and methyl iodide yields the methyl ester, which gives with ammonia pircamidé. Picric acid forms many well-defined salts, of a yellow or red-brown colour. It also yields crystalline compounds with many aromatic hydrocarbons and bases. It imparts a yellow colour to wool and silk. The chief application of picric acid and its salts is in the manufacture of explosives. When ignited, picric acid burns quietly with a smoky flame. and it is very difficult to detonate by percussion; its salts, however, are more readily detonated. The more important picric powders are melinite, believed to be a mixture of fused picric acid and gun-cotton; lyddite, the British service explosive, and skimose, the Japanese powder, both supposed to be identical with the original melinite; Brugère's powder, a mixture of 54 parts of ammonium picrate and 45 parts of saltpetre; Designolle's powder, composed of potassium picrate, saltpetre and charcoal; and ammonite, invented by Stephen Emmens, of the United States. It may be detected by the addition of an aqueous solution of potassium cyanide, with which it gives a violet-red coloration, due to the formation of isopurpuric acid. R. Anschutz (Ber., 1884, 17, p. 430) estimates picric acid by precipitation with acridine.

PICRITE (from Gr. πικρός, bitter, because these rocks are rich in magnesia, a base which forms bitter salts), a rock belonging to the ultrabasic group, and consisting mainly of olivine and augite often with hornblende and biotite and a greater or less amount of plagioclase felspar. The picrites are of "hypabyssal" origin and in their natural occurrence are connected with dolerites (diasbases and teschenites). The distinction between them and the peridotites, which have an essentially similar composition, is not easy to define, but the peridotites accompany the true plutonic rocks, such as gabbro, norite and pyroxenite, are often very coarsely crystalline, and form large bosses and laccolites, while the picrites usually are found in sills or intrusive sheets.

In hand specimens the picrites are dark green to black; the absence or scarcity of lath-shaped plagioclase felspars distinguishes them from diabases and they rarely have the lustre-mottling which is a characteristic of the peridotites. Since they contain much olivine they readily decompose, passing into deep green and brown incoherent masses in which are embedded rounded lumps of harder consistency. They have a high specific gravity (about 3-6) and may be distinctly magnetic, because they are rich in iron ores. Porphyritic structure is rare though occurring sometimes in the rocks known as picrite-porphyrites; the phenocrysts are olivine and augite. There is seldom any fine-grained or glassy groundmass, and the typical microstructure is holocrystalline, moderately fine grained and somewhat poikilitic. Olivine is abundant in rounded pale green crystals. It may form one half of the rock but rarely more than this. The augite is generally brown or reddish-brown, sometimes violet, and tends to enclose the olivine, yielding poecilitic aggregates. Brown hornblende often occurs as marginal growths around the pyroxene and is so abundant as to replace augite to a large extent; rocks of this class are known as hornblende-picrites. Bright green or pale-green hornblende are less frequently present, and in many cases are really of secondary origin. Deep brown biotite is a frequent accessory mineral and both biotite and hornblende sometimes enclose olivine. A small amount of basic plagioclase occurs in many picrites; apatite, iron oxides, chromite and spinels are minor ingredients seldom altogether absent.
PICROTOXIN—PICTON

The minerals of picrites are very frequently decomposed. Serpentine partly or wholly replaces olivine, forming radiate fibrous masses which are green, yellow or red in microscopic sections. Sometimes hornblende (pilite), talc, chlorite and mica appear as secondary products after olivine. The augite passes into chlorite or into green fibrous or platy amphibole. Hornblende and biotite are often fresh whilst the other components are much altered. The felspar is rarely in good preservation but yields epidote, prehnite, sericite, kaolin; calcite and analcite are abundant in some weathered picrites.

Rocks of this type are well represented in Great Britain. In the central valley of Scotland several masses of picrite have been discovered that resemble those associated with olivine-basaltic trachytes. One of these forms the island of Inchcolm in the Firth of Forth, another lies near Bathgate (in Linlithgowshire), and there are others at Aberdour (Fife), Androssan and Barnton (Midlothian). The picrites of the Midlothian district contain augite, biotite and hornblende, and chlorite is very abundant. Picrites occur in several parts of Germany, notably in the Devonian rocks of the Fichtelgebirge and Nassa, where they accompany diabases and porphyrobasalites like those of Cornwall and Devonshire. In the Rock of Ages, Picton and other picrites are the only tecthene rocks known in Central Scotland. In some of the continental picrites enstatite is present but is rare. In North America picrites occur among the igneous rocks on the Hudson river and in Alabama and Montana. (J. S. F.)

PICROTOXIN, a neutral principle obtained from the Cocculus indicus, which is the fruit of the Anamirta paniculata. It is used in medicine externally as an antiperspirant. Internally it has been successfully used to check the night-sweats of phthisis. In large doses it is a powerful poison, causing unconsciousness, delirium, convulsions, gastro-enteritis and stimulation of the respiratory centre followed by paralysis, from which death sometimes results. Formerly low class publicans sometimes added Cocculus indicus herbes to beer to increase the intoxicating effects. Its chemical formula is CsH402O4. H2O.

PICTET DE LA RIVE, FRANCOIS (1800-1872), Swiss zoologist and entomologist, was born in Geneva on the 27th of September 1800. He graduated B. éc. Sc. at Geneva in 1820, and pursued his studies for a short time at Paris, where under the influence of Cuvier, de Blainville and others, he worked at natural history and comparative anatomy. On his return to Geneva in 1830 he assisted A. P. de Candolle by giving demonstrations in comparative anatomy. Five years later, when de Candolle retired, Pictet was appointed professor of zoology and comparative anatomy. In 1846 his duties were restricted to certain branches of zoology, including geology and palaeontology, and he continued to teach until 1859, when he retired to devote his energies to the museum of natural history and to special palaeontological work. He was rector of the academy from 1847 to 1859, and again from 1866 to 1868. He was for many years a member of the Representative Council of Geneva, and in 1862 President of the Constituent Assembly. His earlier published work related chiefly to entomology, and included Recherches pour servir à l'histoire et à l'anatomie des Phrygaides (1834) and two parts of Histoire naturelle, générale et particulière des insectes Neoptères (1842-1845). Feeling the want of a hand-book, he prepared his Traité élémentaire de paléontologie (4 vols. 1844-1846). In the first edition Pictet, while adopting the hypothesis of successive creations of species, admitted that some may have originated through the modification of pre-existing species. In 1852 he entered further into the probable transformation of some species, and discussed the independence of certain faunas, which did not appear to have originated from the types which locally preceded them. He now directed his attention to the fossils of his native country, more especially to those of the Cretaceous and Jurassic strata, and in 1854 he commenced the publication of his great work, Materiaux pour la paléontologie suisse, a series of quarto memoirs, of which six were published (1854-1873). In this work Pictet was aided and from de la Porte and others. Pictet also brought out Mélanges paléontologiques (1863-1868). He died at Geneva on the 15th of March 1872.

PICTON, SIR THOMAS (1758-1819), British general, was the younger son of Thomas Picton, of Poyston, Pembrokeshire, where he was born in August 1758. In 1771 he obtained an ensign's commission in the 12th regiment of foot, but he did not join until two years afterwards. The regiment was then stationed at Gibraltar, where he remained until he was made captain in the 75th in January 1778, when he returned to England. The regiment was disbanded five years later. On the occasion of its disbandment Picton quelled a mutiny amongst the men by his prompt personal action and courage, and was promised a majority in reward for his conduct. This, however, he did not receive, and after living in retirement on his father's estate for nearly twelve years, he went out to the West Indies in 1794 on the strength of a slight acquaintance with Sir John Vaughan, the commander-in-chief, who made him his aide-de-camp and gave him a captaincy in the 7th foot. Shortly afterwards he was promoted major. Under Sir Ralph Abercromby, who succeeded Vaughan in 1795, he took part in the capture of St Lucia (for which he was promoted lieutenant-colonel) and in that of St Vincent. After the reduction of Trinidad Abercromby made him governor of the island. He administered the island with such success that the inhabitants petitioned against the retrocession of the island to Spain, and their protest, with Picton's and Abercromby's representations, ensured the retention of Trinidad as a British possession. In October 1801 he was gazetted brigadier-general. But by this time the rigour of his government, as reported by his enemies, had led to a demand by humanitarians at home for his removal. Colonel William Fullarton (1754-1808) procured the appointment of a commission to govern the island, of which he himself was the senior member, Captain (afterwards Admiral Sir Samuel) Hood the second, and Picton himself the junior. Picton thereupon tendered his resignation, and Hood, as soon as the nature of Fullarton's commission came to his knowledge, quelled it (1803). On this his way home Picton took part with great credit in military operations in St Lucia and Tobago. Realizing, however, that the attacks upon him were increasing in virulence, he quickly returned to England, and in December 1803 he was arrested by order of the privy council. He was tried in the court of king's bench before Lord Ellenborough in 1806 on a charge of unlawfully applying torture to extort a confession from Luis Calderon, a mulatto woman of loose character who was charged, along with a man, with robbery. The torture consisted in compelling the woman to stand on one leg on a flat-headed peg for one hour. The punishment was ordered under Spanish law (which in default of a fresh code Picton had been appointed to administer in 1831) by the local alcalde, and approved by Picton. On these grounds the court returned a merely technical verdict of guilty, which was superseded in 1808 by a special verdict on retrial. It should be mentioned that the inhabitants of the island, who had already given him a sword of honour, and had petitioned the king not to accept his resignation, subscribed £4000 towards his legal expenses, which sum Picton contributed in return to the relief of the suffering caused by a widespread fire in Port of Spain. He had meanwhile been promoted major-general, and in 1809 he had been governor of Flushing during the Walcheren expedition. In 1810, at Wellington's request, he was appointed to command the expedition from Spain in 1810. For the remaining years of the Peninsular War, Picton was one of Wellington's principal subordinates. The commander-in-chief, it is true, never reposed in him the confidence that he gave to Beresford Hill and Craufurd. But in the resolve, thorough and punctual execution of a well-defined task Picton had no superior in the army. His début,
owing partly to his naturally stern and now embittered temper, and partly to the difficult position in which he was placed, was unfortunate. On the Coa in July 1810 Craufurd's division became involved in an action, and Picton, his nearest neighbour, refused to support him, as Wellington's direct orders were to avoid an engagement. Details of the incident will be found in Oman, *Peninsular War*, vol. iii. Shortly after this, however, at Busaco, Picton found and used his first great opportunity for distinction. Here he had a plain duty, that of repulsing the French attack, and he performed that duty with a skill and resolution which indicated his great powers as a troop-leader. After the winter in the lines of Torres Vedras, he added to his reputation and to that of his division, the 3rd, at Fuentes d'Omor. In September he was given the local rank of lieutenant-general, and in the same month the division won great glory by its rapid and orderly retreat under severe pressure from the French cavalry at El Bodon. In October Picton was appointed to the colonelcy of the 77th regiment. In the first operations of 1812 Picton and Craufurd, side by side for the last time, stormed the two breaches of Ciudad Rodrigo, Craufurd and Picton's second in command, Major-General Mackinnon, being mortally wounded. At Badajoz, a month later, the successful storming of the fortress was due to his daring self-reliance and penetration in converting the secondary attack on the castle, delivered by the 3rd division, into a real one. He was himself wounded in this terrible engagement, but would not leave the ramparts, and the day after, when recently inherited a fortune, he gave every survivor of his command a guinea. His wound, and an attack of fever, compelled him to return to England to recruit his health, but he reappeared at the front in April 1813. While in England he was invested with the collar and badge of a K.B. by the prince regent, and in June he was made a lieutenant-general in the army. The conduct of the 3rd division under his leadership at the battle of Vittoria and in the engagements in the Pyrenees raised his reputation as a resolute and skilful fighting general to the highest point. Early in 1814 he was offered, and at length accepted a high command in the Anglo-Dutch forces, consisting of Wellington's army and the command of the British forces operating on the side of Catalonia. He thus bore his share in the Orthez campaign and in the final victory before Toulouse.

On the break-up of the division the officers presented Picton with a valuable service of plate, and on the 24th of June 1814 he received for the seventh time the thanks of the House of Commons for his great services. Somewhat to his disappointment he was not included amongst the generals who were raised to the peerage, but early in 1815 he was made a G.C.B. When Napoleon returned from Elba, Picton, at Wellington's request, accepted a high command in the Anglo-Dutch forces, of which he was general, and at Quatre Bras on the 16th of June, but concealed his wound and retained command of his troops, and at Waterloo on the 18th, while repulsing with impetuous valor "one of the most serious attacks made by the enemy on our position," he was shot through the head by a musket ball. His body was brought home to London, and buried in the family vault at St George's, Hanover Square. A public monument was erected to his memory in St Paul's Cathedral, by order of parliament, and in 1823 another was erected at Caramarthen by subscription, the king contributing a hundred guineas thereto.

See Robinson's *Life of Sir Thomas Picton* (London, 1836), with which, however, compare Napier's and Oman's histories of the Peninsular War as to controversial points.

PICTOU, a seaport, port of entry, and capital of Pictou county, Nova Scotia, 90 m. N.E. by N. of Halifax, on a branch of the Intercolonial railway. Pop. (1901), 3235. It has several valuable industries, and is the shipping port for the adjacent coal-mines. The Academy, founded in 1818, played an important part in the early educational history of the province, and still enjoys a high reputation.

PICUS, in Roman mythology, originally the woodpecker, the favourite bird and symbol of Mars as the god of both nature and war. He appears later as a spirit of the forests, endowed with the gift of prophecy, haunting springs and streams, with a special sanctuary in a grove on the Aventine. As a god of agriculture, especially connected with manuring the soil, he is called the son of Ceres (from stercus, dung; a name of Saturn). Again, Picus is the first king of Latium, son of Saturn and father of Faunus. Virgil (Aen. vii. 170) describes the reception of the ambassadors of Aeneas by Latins in an ancient temple or palace, containing figures of his divine ancestors, amongst them Picus, famous as an augur and soothsayer. According to Ovid (Metam. xiv., 320), Circe, while gathering herbs in the forest, saw the youthful hero out hunting, and immediately fell in love with him. Picus rejected her advances, and the goddess in her anger changed him into a woodpecker, which pecks impetuously at the branches of trees, but still retains prophetic powers. The purple cloak which Picus was fastened in a golden clasp is preserved in the plumage of the bird, the simplest form of art, he was represented by a wooden pillar surmounted by a woodpecker; later, as a young man with the bird upon his head.

PICUMNUS is merely another form of Picus, and with him is associated his brother and double PLUMNUS. Picumnus, a rustic deity (like Picus) and husband of Pomona, is specially concerned with the manuring of the soil and hence called Stergusanus, while Plumnus is the inventor of the pounding of grain, so named from the pester (plium) used by bakers. Under a different aspect, the pair were regarded as the guardians of women in childbirth and of new-born children. Before the child was taken from the mother, he was recognized by the father, a couch was set out for them in the atrium, where their presence guarded it from all evil. Augustine (De civitate dei, vi. 9) mentions a curious custom: to protect a woman in childbirth from the influence of the evil eye on the part of Silvanus, the assistance of three deities was invoked—Intercedona (the healer), Plumnus (the pouncer) and Devera (the sweeper). These deities were symbolically represented by three men who went round the house by night. One smote the threshold with an axe, another with a pester, the third swept it with a broom—three symbols of culture (for trees were hewn down with the axe, grain pounded with the pester, and the fruits of the field swept up with the broom). In modern coal-country they are called "pussin, posey and stiver." A.T.

PIDGIN [or PIGEON] ENGLISH, the lingua franca of the seaports of China, the Straits Settlements in the Far East, consisting in a jargon of corrupted English words with some intermixture of Portuguese and Malay, following Chinese idiomatic usage. It is employed as a means of communication between foreigners and the native Chinese. The word "pidgin" is the Chinese corruption of "business." **PIE.** (i) The name of the bird more generally known as the magpie (p.i.). The word comes through the French from Lat. pica (q.v.). It is probably from the black and white or spotted appearance of the bird that the name "pie" or "pye" (Lat. pica) was given to the ordinal, a table or calendar which gave the services for the fixed days, and in which that for the New Year, with its feasts, was put. The word is sometimes used for the whole of the animal. (ii) A dish made of meat, fish or other ingredients, also of vegetables or fruit, baked in a covering of pastry; in English usage, where "fruit" is the ingredient, the dish is generally called a "tart," except in the case of "apple-pie." The word appears early in the 14th century of meat or fish pies. The expression "to eat humble-pie;" i.e. to make an apology, to retract or recant, is a facetious adaptation of "umbles" (O. Fr. nombles, connected with Lat. lambus, loin or umbilicus, navel), the inner parts of a deer, to "humble" (Lat. humilis, lowly). An "umble-pie," made of the inner parts of a deer or other animal, was once a favourite dish. "Printers' pie," i.e. a mass of confused type, is a transferred sense of "pie," the dish, or of "pie," the ordinal, from the difficulty of decipherment. **PIEDMONT** (Ital. Piemonte; Low Lat. Pedemones and Pedemontium), a territorial division (compartmenti) of northern
PIENZA—PIER

Italy, bounded N. by Switzerland, W. by France, S. by Liguria and E. by Lombardy. Physically it may be briefly described as the upper gathering-ground and valley of the river Po; enclosed on all sides except towards the Lombard plain by the various arms of the Pennine, Gragna, Cottian, Maritime and Ligurian Alps. In 1859 it was divided into the four provinces of Alessandria, Cuneo, Novara and Torino (Turin). It has an area of 11,340 sq. m. The people are chiefly engaged in agriculture—growing wheat, maize and rice, chestnuts, wine and hemp; in the reeling and threading of flax and in the manufacture of cotton, woollens and clothing; there are also considerable manufactures at Turin, Savigliano, &c. The Piedmontese dialect has been rather strongly influenced by French. The chief towns in the several provinces are as follows, with their population, in thousands—Alessandria (72,100), Asti (39,251), Casale Monferrato (31,570), Novi Ligure (17,868), Torino (17,419), Acqui (13,940), Valenza (10,056), Ovada (10,284); total of province 825,745, number of communes 343; Cuneo (26,879), Mondovi (18,682), Fossano (18,175), Savigliano (17,340), Saluzzo (16,028), Brâ (15,821), Alba (13,637), Boves (10,137); total of province 670,504, number of communes 263; Novara (44,249), Vercelli (30,470), Biella (10,267), Trino (12,138), Borgomanero (10,131); total of province 763,830; number of communes, 437; Turin (329,661), Pinerolo (18,639), Carmagnola (11,721), Ivrea (11,606), Moncalieri (11,401); total of province 1,137,144; number of province 3,407,814 in 1859, and in 1901 3,407,403. The large number of communes is noticeable, as in Lombardy, and points to a village life which, owing to greater insecurity and the character of the country, is not to be found in central and southern Italy as a whole. There are numerous summer resorts in the Alpine valleys. The chief railway centres are Turin, communicating with the Mont Cenis line, and with the Riviera by the railway over the Col di Tenda (in process of construction), Novara, Vercelli, Asti, Alessandria, Novi. The communications with Liguria are difficult owing to the approach of the mountains to the coast, and the existing lines from Genoa to Turin and Milan are hardly sufficient to cope with the traffic.

Piedmont in Roman times until 40 B.C. formed a part of Gallia Transpadana, and in Augustus' division of Italy formed with what was later known as Lombardy the 11th region. It formed part of the Lombard kingdom, and it was not till about A.D. 1000 that the house of Savoy (q.v.) arose. The subsequent history of Piedmont is that of its dynasty.

PIENZA, a town of Tuscany, Italy, in the province of Siena, 9 m. west of the town of Montepulciano by road, 1611 ft. above sea-level. Pop. (1901), 2730 (town); 3856 (commune). The place was originally called Corsignano and owes its present name to Aenneas Silvius Piccolomini, Pope Pius II. (q.v.) who was born here in 1405. The buildings which he caused to be erected by Bernardo Rossellino in 1460-1463 form a noble group of early Renaissance architecture round the Piazza del Duomo. The latter retains Gothic details in the interior, but the façade is simple work. The other three sides are occupied by the episcopal and municipal palaces, and the Palazzo Piccolomini; the last, resembling the Palazzo Rucellai at Florence, is the finest, and in front of it is a beautiful fountain. The episcopal palace contains a museum with some fine ecclesiastical vestments, enamels and other works of art.

PIER (older forms per or per; from Med. Lat. pera; the word is of obscure origin, and the connexion with Fr. pierre, Lat. petra, stone, is doubtful; equivalents are Fr. piedrot, pilier, trumeau; Ital. pia; Ger. Pfeiler), the term given in architecture to a vertical support in masonry or brickwork, usually rectangular or annular on plan, which carries an arch or superstructure. The term is also sometimes given to the great circular columns which in some English cathedrals and churches carry the nave arches. In early Christian churches, when antique columns, such as abound in Rome, were not procurable, square piers took the place of columns and sometimes alternated with them. The introduction of vaulting, however, in the 11th century, necessitated a support of much greater dimensions than those which had been deemed sufficient when the roof was of timber only, and led to the development of the compound or clustered pier. To give extra support to the subordinate arches of the nave arcade, semicircular shafts or pilasters were added, carried up to the transverse and diagonal ribs of the main vault. In Romanesque work the pier was generally square on plan with semicircular shafts attached, the angles of the pier being worked with smaller shafts. As the rings or orders of the nave arches increased in number, additional shafts were added to carry them, and the pilaster facing the nave had central and side shafts rising to carry the transverse and diagonal ribs of the vault; this development of the compound pier obtains throughout Europe in all vaulted structures. In the Early English period the piers became loftier and lighter, and in most important buildings a series of clustered columns, frequently of marble, are placed side by side, sometimes set at intervals round a circular centre, and sometime almost touching each other. These shafts are often wholly detached from the central pier, though grouped round it, in which case they are almost always of Purbeck or Betersden marbles. In Decorated work the shafts on plan are very often placed round a square set angle-wise, or a lozenge, the long way down the nave; the centre or core itself is often worked into hollows or other mouldings, to show between the shafts, and to form part of the composition. In this and the last of the several styles there is generally a fillet on the outer part of the shaft, forming what has been called a "heel moulding" (q.v.). They are also often tied together by bands, formed of rings of stone and sometimes of metal. About this period, too, these intermediate mouldings run up into and form part of the arch moulds, there being no impost. This arrangement became much more frequent in the Perpendicular period; in fact it was almost universal, the commonest section being a lozenge set with the long side from the nave to the aisle, and not towards the other arches, as in the Decorated period, with four shafts at the angles, between which were shallow mouldings, one of which was in general a wide hollow, sometimes with wave moulds. The small columns at the jambs of doors and windows, and in arcades, and also those attached to piers or standing detached, are generally called "shafts" (q.v.).

The term pier is sometimes applied to the solid parts of a wall between windows or voids, and also to the isolated masses of brickwork or masonry to which gates are hung. (R. P. S.)

Piers of Bridges.—The piers of bridges and viaducts on land are constructed of masonry or brickwork and occasionally, in the case of high piers, of open branded ironwork, as exemplified by the old Crumlin viaduct in Wales and the Pecos viaduct in Texas. These piers, besides being proportioned in cross-section to the weight they have to support, are widened out at their base, so called "flared" piers to the base, and are strengthened by the stratum on which it rests without risk of settlement. Special provisions have to be made for the foundations of piers where the ground is soft for some depth, or loose water-bearing strata are encountered, and especially where the piers of large bridges crossing rivers have to be constructed under water.

In soft ground, bearing piles driven down to a firm stratum, and surmounted by a planked floor or a layer of concrete, provide a convenient foundation for a pier; and in places where timber is abundant, wooden cribs filled with rubble stone or concrete have been used in the United States for raising the foundations for piers out of water. For river piers, where a firm, watertight stratum is found at a moderate depth below the river-bed, the site is often enclosed within a cofferdam or a plate iron caisson carried down into the stratum and raised out of water; and then, after the water has been pumped out and the surface layers removed, the pier is readily built within the enclosure in the open air. When, however, a river-bed consists of silt, sand or other soft materials extending down to a considerable depth, brickwork wells are gradually sunk to a firm stratum by removing the material within them with grubs, and on them the piers are built out of water; or bottomless caissons are carried down by excavating their interiors under compressed air, and the piers are built on top of them within a plate-iron enclosure, a system
adopted for the piers of the Brooklyn, St Louis, Forth and other large bridges, and essential for forming foundations on sloping rock, such as was encountered in places under the Firth of Forth.

The methods indicated above as employed for the foundations of the piers of bridges under favourable conditions belong equally to the foundations of other structures (see Foundations); but there are some methods which, by combining bridge piers and their foundations in a single structure, appertain entirely to piers. Thus iron screw piles, sunk by turning into the soft bed of a river till they reach a firm stratum or one sufficiently consolidated by the superincumbent layers to enable it to support the wide blades of the screws with the weight imposed on them, were formerly often arranged in converging clusters joined together at the top, so as to serve as the piers of bridges having several comparatively small spans, and intended for carrying lightly constructed railways across rivers in India and elsewhere. Hollow, cast-iron, cylindrical piles also, with a broad circular disk at the bottom to increase their bearing surface, have been used for piers founded in sandy or silty strata bolted together with a specially strong bottom ring, sometimes made of wrought iron and having a cutting edge, have been often employed for the construction of the river piers of bridges, being gradually carried down to a watertight stratum by excavating inside, and subsequently filled up solid with concrete and brickwork; the piers of the Charing Cross and Cannon Street bridges across the Thames are notable instances of the adoption of this method, which is well illustrated by the piers of the bridges across the River Chitravati in India (fig. 2). Sometimes, instead of two or more independent cylinders being sunk, the whole site of a pier is enclosed within a wrought-iron caisson, usually divided into sections by vertical partitions, which is sunk and filled up solid in the same way as cylinders, a system adopted, for instance, for the piers of the bridge across the Hawkesbury River in New South Wales.

Promenade Piers.—The term pier is often applied to works sheltering harbours, such as the Tynemouth piers, which are strictly breakwaters. Landing stages also, whether solid or open, have for a long time been called piers, as the Admiralty Pier and the Prince of Wales’s Pier at Dover; but the open promenade piers which form a common feature at seaside resorts are of the type best known to the general public. These piers are supported upon open pilework of timber or iron, and consequently expose little surface to waves in storms and do not interfere with the drift of shingle or sand along the coast (fig. 3). Timber piles are best suited for withstanding the shocks of vessels at landing stages, at which places they are generally used; but since they are subject to the attacks of the teredo, and expose a considerable surface to the waves, iron piles are generally adopted for the main portion of these piers.

The pioneer of these piers was the old chain pier at Brighton, which was erected in 1822–1823. It was founded upon oak piles, was 1136 ft. long, and had a timber landing-stage at the end. It consisted of four spans suspended from chains on the model of the Menai Suspension Bridge, then in course of construction, and was destroyed by a gale in December 1896. A wider and more modern type of pier was erected at the west end of Brighton in 1865–1866, of considerable thickness; they are sunk to the requisite depth by lowering a pipe down the inside of the pile to the bottom and emitting a powerful jet of water which, stirring up the soft material and scouring it away from under the disk, causes the pile to descend. This system was first adopted for the piers of a railway viaduct crossing the wide, sandy Kent and Leven estuaries opening into Morecambe Bay (fig. 1). Cast-iron cylinders, consisting of a series of rings formed of segments all and subsequently extended; whilst a new pier was completed in 1900 near the site of the old chain pier, 1700 ft. long. The Southport pier, erected in 1859–1860 and afterwards prolonged, furnishes an example of an iron pier supported on disk piles sunk in sand as described above (fig. 1); whilst the much more commonly used iron screw piles, adopted as early as 1847 for an open landing-pier on the Irish coast at Courtown, which was exposed to a great littoral drift of sand, are shown as the mode of support for the pier

\[\text{FIG. } 3.-\text{Promenade Pier.}\]

at St Leonards (fig. 3). The length given to these promenade piers depends mainly on the slope of the foreshore, which determines the inclination of the steps. A sufficient length of the pier has been reached for steamers of moderate draft to come alongside the end of the pier. Thus, whereas a length of 900 ft. has sufficed for the St Leonards pier on a somewhat steep, shingly beach, the pier at St Leonards is only 450 ft. long. The pier at St Leonards has been built as a shelter for Wight passengers, has had to be carried out about half a mile across a flat alluvial foreshore to reach water deep enough for the access of the steamboats crossing the Solent. The vast sands, moreover, at the outlet of the Riddle estuary, stretching two or three miles in front of Southport at low water of spring tides, have necessitated the construction of a pier 4305 ft. long merely to get out to an old flood-tide channel, which is now completely severed by the sands at low water from all connexion with the river.

(L. F. V.-H.)

PIERCE, FRANKLIN (1804-1869), fourteenth president of the United States, was born at Hillsborough, New Hampshire, on the 23rd of November 1804. His father, Benjamin Pierce (1757-1839), served in the American army throughout the War of Independence, was a Democratic member of the New Hampshire House of Representatives from 1789 to 1823, and was governor of the state in 1827-1828. The son graduated in 1824 at Bowdoin College, at Brunswick, Maine, where he formed a friendship with Nathaniel Hawthorne. Pierce then studied law, and in 1827 was admitted to the bar and began to practise at Hillsborough. He at once took a lively interest in politics, and from 1829 to 1833 served in the state House of Representatives, for the last two years as Speaker. In 1833 he entered the national House of Representatives, and although he achieved no distinction in debate he was a hard worker, and a loyal supporter of the policies of President Jackson. After four years in the House he entered the Senate, being its youngest member. In 1842, before the expiration of his term, he resigned his seat, and at Concord, New Hampshire, began his career at the bar in earnest, though still retaining an interest in politics. In 1845 he declined the Democratic nomination for governor, and also an appointment to the seat in the United States Senate made vacant by the resignation of Judge Levi Woodbury. He accepted, however, an appointment as Federal District Attorney for New Hampshire, as the duties of this office, which he held in 1845-1847, were closely related to those of his profession. In 1846 he again declined public honours, when President Polk invited him to enter the cabinet as attorney-general. Soon after the outbreak of the war with Mexico, in 1846, Pierce occupied the post of Secretary of War, and in 1847 became colonel of the Ninth Regiment (which joined General Winfield Scott at Pueblo on the 6th of August 1847), and later (March, 1847) became a brigadier-general of volunteers. At the battle of Contreras, on the 10th of August 1847, he was thrown from his horse and received severe injuries. At the end of the war he resigned his commission and returned to Concord. In 1850 Pierce became president of a convention assembled at Concord to revive the constitution of the state, and used his influence to secure the removal of those provisions of the constitution of 1793 which declared that only Protestants should be eligible for higher state offices. This amendment passed the constitution on April 15, 1852, but was rejected by the electorate of the state; a similar amendment was adopted by popular vote in 1877. In January 1852 the legislature of New Hampshire proposed him as a candidate for the presidency, and when the Democratic national convention met at Baltimore in the following June the Virginia delegation brought forward his name on the thirty-fifth ballot. Although both parties had declared the Compromise of 1850 a finality, the Democrats alone were thoroughly united in support of this declaration, and therefore seemed to offer the greater prospect of peace. This fact, combined with the colourless record of their candidate, enabled them to sweep the country at the November election. Pierce received 254 electoral votes, and Gen. Winfield Scott, his Whig opponent, only 42. The Democrats carried every state except Massachusetts, Vermont, Kentucky and Tennessee. No president since James Monroe had received such a vote.

Pierce was the youngest man who had as yet been elevated to the presidency. For his cabinet he chose William L. Marcy of New York, secretary of state; Jefferson Davis of Mississippi, secretary of war; James Guthrie (1792-1860) of Kentucky, secretary of the treasury; James C. Dobbin (1814-1852) of North Carolina, secretary of the navy; Robert McClelland (1807-1880) of Michigan, secretary of the interior; James Campbell (1815-1853) of Pennsylvania, postmaster-general; and Caleb Cushing of Massachusetts, attorney-general. This was the ablest cabinet in American history that has continued unbroken throughout an entire administration. Although Pierce during his term in the Senate had severely criticized the Whigs for their removals of Democrats from office, he himself now adopted the policy of replacing Whigs by Democrats, and the country acquiesced. Pierce had no scruples against slavery, and opposed anti-slavery agitation as tending to disrupt the Union. The conduct of foreign relations was on the whole the most creditable part of his administration. The Kossta Affair (1853) gave the government an opportunity vigorously to assert the protection it would afford those in the process of becoming its naturalized citizens.

When the British government refused to prevent recruiting for the Crimean War by their representatives in America, their minister, John F. Crampton, received his passports, and the exequaturs of the British consuls at New York, Philadelphia and Cincinnati were revoked. A commercial treaty was negotiated with Japan in 1854 after Perry's expedition in the previous year. As an avowed expansionist, Pierce sympathized with the filibuster government set up in Nicaragua by William Walker, and finally accorded it recognition. It was during this term also that the Gadsden Purchase was consummated, by which 45,535 sq. m. of territory were acquired from Mexico, and that three routes were surveyed for railways from the Mississippi river to the Pacific coast.

When the Democratic national convention met at Cincinnati in June 1856, Pierce was an avowed candidate for renomination, but as his attitude on the slavery question, and especially his subserviency to the South in supporting the pro-slavery party in the Territory of Kansas, had lost him the support of the Northern wing of his party, the nomination went to James Buchanan. After retiring from the presidency Pierce returned to Concord, and soon afterwards went abroad for a three years' tour in Europe. Many Southern leaders desired his renomination by the Democratic party in 1860, but he received such a storm of opposition at the convention that he withdrew. After his return to America he remained in retirement at Concord until the day of his death, the 8th of October 1869.

Pierce was not a great statesman, and his fame has been overshadowed by that of Benton, Calhoun, Clay and Webster. But he was an able lawyer, an orator of no mean reputation, and a brave soldier. He was a man of fine appearance and courtly manners, and he possessed personal magnetism and the ability to make friends, two qualities that contributed in great measure to his success.

A collection of Pierce's correspondence has been published in the American Historical Review, v. 110-127, 350-370. D. W. Bartlett's Franklin Pierce (Auburn, New York, 1852), and Nathaniel Hawthorne's Franklin Pierce (Boston, 1852), are two "campaign" biographies of Pierce, and are of the greatest service in the Life, Administration and Times of Franklin Pierce (Chicago, 1888), being vol. xiv. of his Republic, is a more critical work, but inaccurate as to details. J. E. Cooke's Review of the Administration of General Pierce (New York, 1854) and Anna E. Carroll's Review of Pierce's Administration (Boston, 1856) are hostile anti-administration tracts. The best accounts of Pierce's administration are to be found in James Schouler's History of the United States, vol. v. (new ed., New York, 1894); J. F. Rhodes's History of the United States, vols. i. and ii. (New York, 1893-1894); and J. W. Burgess's Middle Period (New York, 1900).

PIERO DI COSIMO (1462-1521), the name by which the Florence painter Pietro di Lorenzo is generally known. He was born at Florence in 1462, and worked in the studio of Cosimo Roselli (from whom he derived his popular name). Other influences that can be traced in his work are those of Filippino Lippi, Luca Signorelli, and Leonardo da Vinci, and, as has been recently suggested by Professor R. Muther, that of Hugo van der Goes, whose Portinarl altar-piece (now at the
Pierre—Pierrepont

Pierrepont (Pierrepont) of S. Maria Novella in Florence) helped to lead the whole of Florentine painting into new channels. From him, most probably, he acquired the love of landscape and the intimate knowledge of the growth of flowers and of animal life. The influence of Hugo van der Goes is especially apparent in the "Adoration of the Shepherds," at the Berlin Museum. He had the gift of a fertile fantastic imagination, which, as a result of a journey to Rome in 1482 with his master, Rosselli, became directed towards the myths of classic antiquity. He proves himself a true child of the Renaissance in such pictures as the "Death of Procris," at the National Gallery, the "Mars and Venus," at the Berlin Gallery, the "Perseus and Andromeda" series, at the Uffizi in Florence, and the "Hylas and the Nymphs," belonging to Mr Benson. If, as we are told by Vasari, he spent the last years of his life in gloomy retirement, the explanation probably is due to Savonarola, under whose influence he turned his attention once more to religious art. The "Immaculate Conception," at the Uffizi, and the "Holy Family," at Dresden, best illustrate the religious fervour to which he was stimulated by the stern preacher.

With the exception of the landscape background in Rosselli's fresco of the "Sermon on the Mount," in the Sistine Chapel, we have no record of any fresco work from his brush. On the other hand, he enjoyed a great reputation as a portrait painter, though the only known examples that can be definitely ascribed to him are the portrait of a warrior, at the National Gallery, (Nov. 1493), the so-called "Bella Simonetta," at Chantilly, the portrait of Dr. John Bull, of San Gimignano, and his father, at the Hague, and a head of a youth, at Dulwich. Other portraits of Pierrepont excelled in design pageants and triumphal processions for the pleasure-loving youths of Florence, and give a vivid description of such a procession at the end of the carnival of 1597, which illustrated the triumph of death. Piero di Cosimo exercised considerable influence upon his fellow pupils Albertinelli and Bartolommeo della Porta and was the master of Andrea del Sarto. Examples of his work are also to be found at the Louvre in Paris, the Harrach and Liechtenstein collections in Vienna, the Borghese Gallery in Rome, the Spedale degli Innocenti in Florence, and in the collections of Mr. John Burke and Colonel Cornwallis in London. A "Magdalen" from his brush was added to the National Gallery of Rome in 1907.

See Piero di Cosimo, by F. Knapp (Halle, 1899); Piero di Cosimo, by H. Haberfeld (Breslau, 1901).

PIERRE, the capital of South Dakota, U.S.A., and the county-seat of Hughes county, situated on the east bank of the Missouri river, opposite the mouth of the Bad river, about 185 m. N.W. of Yankton. Pop. (1805) 2709; (1910) 3626. Pierre is served by the Chicago & North-Western railway; the Missouri is navigable here, but river traffic has been practically abandoned, the principal trade being in the state capital (1909) and the post office building. Pierre has a public library, and is the seat of the Pierre Industrial School (co-educational, opened in 1890), a government boarding school (non-reservation) for Indian children. The city has a large trade in livestock, and is a centre for the mining districts of the Black Hills and for a grain-growing country. Natural gas is used for lighting, heating and power. A fur-trading post, Fort La Framboise, was built in 1817 by a French fur-trader (from whom it took its name) at the mouth of the Teton or Little Missouri river (now called the Bad River), on or near the site of the present village of Fort Pierre (pop. in 1910, 792). In 1822 Fort Tecumseh was built about 2 m. up-stream by the Columbia Fur Company, which turned it over in 1827 to the American Fur Company. The washing away of the river bank caused the abandonment of this post and the erection about a mile farther up-stream, and a short distance west of the river, of Fort Pierre Chouteau (later called Fort Pierre), occupied in 1832, and named in honour of Pierre Chouteau, jun. (1789-1861). For twenty years thereafter Fort Pierre was the chief fur-trading depot of the Upper Missouri country. In 1855 the United States government bought the post building and other property for $45,000, and laid out around them a military reservation of about 270 sq. m. The fort was the headquarters of General William S. Harney (1806-1889) in his expedition against the Sioux in 1856, and in March of that year an important council between General Harney and the chiefs of all the Sioux bands, except the Blackfeet, was held here. Pierre was abandoned in 1857. Pierre was laid out in 1880, was incorporated as a village in 1883, and was chartered as a city in 1900.

PIERRE DE CASTELNAU (d. 1208), French ecclesiastic, was born in the diocese of Montpellier. In 1190 he was archbishop of Maguelonne, and was appointed by Pope Innocent III. as one of the legates for the suppression of heresy in Languedoc. In 1202, when a monk in the Cistercian abbey of Fontfrôde, Narbonne, he was designated to similar work, first in Toulouse, and afterwards at Viviers and Montpellier. In 1207 he was in the Rhone valley and in Provence, where he became involved in the strife between the count of Baux and Raymond, count of Toulouse, by one of whose agents he was assassinated on the 1st of January 1207. He was beheaded in the year of his death by Pope Innocent III.

PIERREFONDS, a town of northern France, in the department of Oise, 9 m. S.E. of Compiègne by road. Pop. (1906), 1482. It is celebrated for its feudal stronghold, a masterpiece of modern restoration. The building is rectangular in shape, with a tower at each corner and at the centre of each of the walls, which are strengthened by crenelation and machicolation. A lofty keep defends the principal entrances on the south-west. The interior buildings are chiefly modern, but the exterior reproduces faithfully that of the medieval fortress. Pierrefonds has a church dating from various periods from the 11th to the 16th century, and its mineral springs are in some repute. The château was begun in the last decade of the 14th century by Louis d'Orléans, to whom the domain was given by Charles VI., and finished early in the 15th century. It was subsequently held by the Burgundians, the English and the adherents of the League, from whom it passed to Henry IV. It was dismantled in 1622. The ruins, bought by Napoleon I., were restored, by order of Napoleon III., from 1858 to 1865, under the direction, first of Viollet-le-Duc and afterwards of E. Boeckwillard. The château was restored to the state in 1869 (1878) 98, English politician, was the second son of the earl of Carlisle. Returned to the Long Parliament in 1649 as member for Great Wenlock, he threw his influence on the side of peace and took part for the parliament in the negotiations with Charles I. at Oxford in 1643. Pierrepont was a member of the committee of both kingdoms, and represented the parliamentary party during the deliberations at Uxbridge in 1645; but from that time, according to Clarendon, he forsook his moderate attitude, and "contracted more bitterness and sourness than formerly." This statement, however, is perhaps somewhat exaggerated, as Pierrepont favoured the resumption of negotiations with the king in 1647, and in the following year his efforts on behalf of peace at Newport, where again he represented the parliamentarians, brought upon him some slight censure from Cromwell. For his services at Newport he was thanked by parliament; but he retired from active political life soon afterwards, as he disliked the "purging" of the House of Commons by Colonel Pride and the proceedings against the king. In spite of his Company. Chouteau built (1830-1831) the "Yellowstone," which went up the river to the present site of Pierre in 1831, and was the first steamboat to navigate the upper waters of the Missouri river. Pierre Chouteau lived for some years in New York City, and while living in St. Louis was a member of the convention (1820) which drafted the first constitution of Missouri.
moderate views Pierpont enjoyed the personal friendship of Cromwell; but, although elected, he would not sit in the parliament of 1656, nor would he take the place offered to him in the Protector's House of Lords. When Richard Cromwell succeeded his father, Pierpont was an unobtrusive but powerful influence in directing the policy of the government, and after a short period of retirement on Richard's fall he was early in 1660, a member of the council of state. He represented Nottinghamshire in the Convention Parliament of 1660, and probably was instrumental in saving the lives of some of the parliamentary leaders. At the general election of 1661 he was defeated, and, spending the remainder of his life in retirement, he died in 1678. Pierpont married Elizabeth, daughter of Sir Thomas Harris, Bart., of Tong Castle, Shropshire, by whom he had five sons and five daughters. His eldest son, Robert (d. 1666), was the father of Robert, 3rd earl, William, 4th earl, and Evelyn, 1st duke of Kingston; and his third son, Gervase (1640-1715), was created in 1714 baron Pierpont of Hanslope, a title which became extinct on his death.

PIERROT (Ital. Petrulino), the name given to the leading character in the French pantomime plays since the 18th century; transferred from the Italian stage, and revived especially in recent times. He is always in white, both face and costume, with a loose and daintily clovenish garb, and is represented as of a freakish disposition. Modern pierrot plays have converted the pierrot into a romantic and even pathetic figure.

PIERSON, HENRY HUGO (properly Henry Hugh Pearson), (1815-1873), English composer, was the son of the Rev. Dr Pearson of St John's College, Oxford, where he was born in 1815; his father afterwards became dean of Salisbury. Pierson was educated at Harrow and Trinity College, Cambridge, and was at first intended for the career of medicine. His musical powers were too strong to be repressed, and after receiving instruction from Attwood and A. T. Corfe he went in 1839 to Germany to study under C. H. Kink, Tomaschek and Reissiger. He was elected Reid Professor of Music in Edinburgh in 1844, but, owing to a disagreement with the authorities, he resigned in the following year, and definitely adopted Germany as his country about the same time, making the change in his names noted above. His two operas, Leila (Hamburg, 1848) and Contarini (Hamburg, 1872), have not retained their hold upon the German public as his music to Faust has done, a work which until quite recently was frequently associated with Goethe's drama. He was never recognized in England as he was in Germany, for most of his career fell in the period of the Mendelssohn fashion. His most important work was the oratorio Jerusalem, produced at the Norwich Festival of 1852, and subsequently given in London (Sacred Harmonic Society, 1853) and Würzburg (1852). For the Norwich Festival (at one of the meetings a selection from his Faust music was given with success) he began an oratorio, Hezekiah, in 1869; it was not finished, but was given in a fragmentary condition at the festival of that year. These two large works and a number of Pierson's songs, as well as the three overtures played at the Crystal Palace, reveal undeniable originality and a wealth of melodic ideas. He was weak in contrapuntal skill, and his music was wanting in outline and coherence; but in more fortunate conditions his great gifts might have been turned to better account. He died at Leipzig on the 28th of January 1873, and was buried at Sonning, Berks., of which parish his brother, Canon Pearson, was rector.

PIETAS, in Roman mythology, the personification of the sense of duty towards God and man and the fatherland. According to a well-known story, a young woman in humble circumstances, whose father (or mother?) was cast into prison under sentence of death, without food, managed to gain admittance, and fed her parent with milk from her breast. To commemorate her filial affection a temple was dedicated (18 B.C.) by Manius Aeliaus Glabrio to Pietas in the Forum Holitorium at Rome, on the spot where the young woman had formerly lived. The temple was probably originally vowed by the elder Glabrio out of gratitude for the pietas shown during the engagement by his son, who may have saved his life, as the elder Africanus that of his father at the battle of Ticinum (Livy xxi. 46); the legend of the young woman (borrowed from the Greek story of Mycon and Pero, Val. Max. iv. 4, ext. 1) was then connected with the temple by the identification of its site with the prison. There was another temple of Pietas near the Circus Flaminius, which is connected by Amatucci (Rivista di storia antica, 1903) with the story of the Pietas of C. Flaminius (Val. Max. v. 4, 5), and regarded by him as the real seat of the cult of the goddess, the Pietas of the sanctuary dedicated by Glabrio being a Greek goddess. Pietas is represented on coins as a matron throwing incense on an altar, her attribute being a stork. Typical examples of "piety" are Aeneas and Antoninus Pius, who founded games called Eusebela at Putocli in honour of Hadrian.

See Val. Max. v. 4, 7; Pliny, Nat. hist. vii. 121; Livy xl. 34; Feuss, s.v. "C. Wessow." Religion und Kultur der Römer (1902); F. Kunze, "Die Legende von der guten Tochter," in Jahrbücher für das klassische Altertum (1904), xxxii. 280.

PIETERMARITZBURG, the capital of Natal, situated in 29° 46′ S., 30° 13′ E., 45 m. in a direct line (71 by rail) W.N.W. of Durban. It lies, 2,000 ft. above the sea, north of the river Umsunduzi, and is surrounded by wooded hills. Of these the Town Hill, flat-topped, rises 1,000 ft. above the town. Pop. (1904), 31,119, of whom 15,057 were whites, 10,752 Kaffirs, and 5,280 Indians. The town is laid out on the usual Dutch South African plan—in rectangular blocks with a central market square. The public buildings include the legislative council chambers and the legisive assembly buildings, government house, the government offices, colleges, post office and market buildings. The town-hall, a fine building in a modified Renaissance style (characteristic of the majority of the other public buildings), has a lofty tower. It was completed in 1901, and replaces a building destroyed by fire in 1898. St. Saviour's is the cathedral church of the Anglican community. The headquarters of the Dutch Reformed Church are also in the town. There are monuments of Queen Victoria and Sir Theophilus Shepstone, and various war memorials—one commemorating those who fell in Zululand in 1879, and another those who lost their lives in the Boer War 1899-1902. A large park and botanical gardens add to the attractions of the town. A favourite mode of conveyance is by rickshaw. The climate is healthy and agreeable, the mean annual temperature being 65° F. (55° in June, 75° in February). The rainfall is about 38 in. a year, chiefly in the summer months (Oct.–Mar.), when the heat is tempered by violent thunderstorms.

Pietermaritzburg was founded early in 1839 by the newly-arrived Dutch settlers in Natal, and its name commemorates two of their leaders—Piet Retief and Gerrit Maritz. From the time of its establishment it was the seat of the Volksraad of the Natal Boers, and on the submission of the Boers to the British in 1842 Maritzburg (as it is usually called) became the capital of the country. It was given a municipal board in 1848, and in 1854 was incorporated as a borough. Railway connexion with Durban was made in 1886, and in 1895 the line was extended to Johannesburg. The borough covers 44 sq. m. and includes numerous attractive suburbs. The rateable value is about £4,000,000. Various industries are carried on, including brickmaking, tanning, brewing, and cart and wagon building.

See J. F. Ingram, The Story of an African City (Maritzburg, 1898).

PIETERSBURG, a town of the Transvaal, capital of the Zoutpansberg district, and 177 m. N.N.E. of Pretoria by rail. Pop. (1904), 3,726, of whom 1,620 were whites. The town is pleasantly situated, at an elevation of 4,700 ft., on a small tributary of the Zane river affluent of the Limpopo, and is the place of most importance in the province north of Pretoria. From it roads run to Klein Lelaba and other gold-mining centres in the neighbourhood, and through it passes the old route to Mashonaland, which crosses the Limpopo at Rhodes Drift. The Zoutpansberg district contains a comparatively dense Kaffir population, and a native newspaper is published at Pietersburg.
PIETISM, a movement in the Lutheran Church, which arose towards the end of the 17th and continued during the first half of the following century. The name of Pietists was given to the adherents of the movement by its enemies as a term of ridicule, like that of "Methodists" somewhat later in England. The Lutheran Church had, in continuing Melanchthon's attempt to construct the evangelical faith as a doctrinal system, by the 17th century become a creed-bound theological and sacramentarian institution, which orthodox theologians like Johann Gerhard of Jenn (d. 1637) ruled with almost the absolutism of the papacy. Christian faith had been dislocated from its seat in the heart, where Luther had placed it, to the cold region of the intellect. The dogmatic formulations of the Lutheran Church had usurped the position which Luther himself had assigned to the Bible alone, and as a consequence only they were studied and preached, while the Bible was neglected in the family, the study, the pulpit and the university. Instead of advocating the priesthood of all believers, the Lutheran pastors had made themselves a despotic hierarchy, while they neglected their practical pastoral work. In the Reformed Church, on the other hand, the influence of Calvin had made less for doctrine than the piety of Christian living. The presbyterian constitution gave the people a share in church government, of which the Lutherans lacked, but it involved a dogmatic legislation which imprisoned Christian freedom and fostered self-righteousness.

As forerunners of the Pietists in the strict sense, not a few earnest and powerful voices had been heard bewailing the shortcomings of the Church and advocating a revival of practical and devout Christianity. Amongst them were Jakob Boehme (Behmen), the theosophic mystic; Johann Arndt, whose work on True Christianity became widely known and appreciated; Heinrich Müller, who described the font, the pulpit, the confessional and the altar as the four dumb idols of the Lutheran Church; the theologian, Johann Valentin Andrea, the court chaplain of the landgrave of Hesse; Schuppis, who sought to restore to the Bible its place in the pulpit; and Theophilus Grossebauer (d. 1666) of Rostock, who from his pulpit and by his writings raised "the alarm cry of a watchman in Sion." The direct originator of the movement was Philip Jacob Spener, who combined the Lutheran emphasis on Biblical doctrine with the Reformed tendency to vigorous Christian life. Born at Rappolsweiler, in Alsace on the 13th of January 1659, trained by a devout godmother, who used books of devotion like Arndt's True Christianity, accustomed to hear the sermons of a pastor who preached the Bible more than the Lutheran creeds, Spener was early convinced of the necessity of a moral and religious reformation of the German Church. He studied theology, with a view to the Christian ministry, at Strassburg, where the professors at the time (and especially Sebastian Schmidt) were more inclined to practical Christianity than to theological disputation. He afterwards spent a year in Geneva, and was powerfully influenced by the strict moral life and rigid ecclesiastical discipline prevalent there, and also by the preaching and the piety of the Waldensian professor, Antoine Leger, and the converted Jesuit preacher, Jean de Labadie. During a stay in Tübingen he read Grossebauer's Alarm Cry, and in 1666 he entered upon his first pastoral charge at Frankfurt-Unter-Main, profoundly impressed with a sense of the danger of the Christian life being sacrificed to zeal for rigid orthodoxy. Pietism, as a distinct movement in the German Church, was then originated by Spener by religious meetings at his house (collegia pietatis), at which he repeated his sermons, expounded passages of the New Testament, and induced those present to join in conversation on religious questions that arose. They gave rise to the name "Pietists." In 1675 Spener published his Pia desideria, or Earnest Desires for a Reform of the True Evangelical Church. In this publication he made six proposals as the best means of restoring the life of the Church: (1) the earnest and thorough study of the Bible in private meetings, ecclesiæ in ecclesiæ; (2) the Christian priesthood being universal, the laity should share in the spiritual government of the Church; (3) a knowledge of Christianity must be attended by the practice of it as its indispensable sign and supplement; (4) instead of merely didactic, and often bitter, attacks on the heterodox and unbelievers, a sympathetic and kindly treatment of them; (5) a reorganization of the theological training of the universities, giving more prominence to the devotional life; and (6) a different style of preaching, namely, in the place of pleading rhetoric, the implanting of Christianity in the inner or new man, the soul of which is faith, and its effects the fruits of life. This work produced a widespread influence throughout Germany, and although large numbers of the orthodox Lutheran theologians and pastors were deeply offended by Spener's book, its complaints and its demands were both too well justified to admit of their being point-blank denied. A large number of pastors at once practically adopted Spener's proposals. In Paul Gerhardt the movement found a singer whose hymns are genuine folk poetry. In 1866 Spener accepted an appointment to the court-chaplainship at Dresden, which opened to him a wider though more difficult sphere of labour. In Leipzig a society of young theologians was formed under his influence for the learned study and devout performance of the Bible.

As a school of the Pietists, one of whom was August Hermann Francke, subsequently the founder of the famous orphanage at Halle (1695), commenced courses of expository lectures on the Scriptures of a practical and devotional character, and in the German language, which were zealously frequented by both students and townsmen. The lectures aroused, however, the ill-will of the other theologians and pastors of Leipzig, and Francke and his friends left the city, and with the aid of Christian Thomasius and Spener founded the new university at Halle. The theological chairs in the new university were filled in complete conformity with Spener's proposals. The main difference between the new Pietistic school and the orthodox Lutherans arose from the conception of Christianity as chiefly consisting in a change of heart and consequent holiness of life, while the orthodox Lutherans of the time made it to consist mainly in correctness of doctrine.

Spener died in 1705; but the movement, guided by Francke, fertilized from Halle the whole of Middle and North Germany. Among its greatest achievements, apart from the philanthropic institutions founded at Halle, were the organization of the Moravian Church in 1727 by Count von Zinzendorf, Spener's godson and a pupil in the Halle Orphanage, and the establishment of the great Protestant missions, Zinzenthal and others being the pioneers of an enterprise which until this time Protestantism had strangely neglected.

Pietism, of course, had its weaknesses. The very earnestness with which Spener had insisted on the necessity of a new birth, and on a separation of Christians from the world, led to exaggeration and fanaticism among followers less distinguished than himself for wisdom and moderation. Many Pietists soon maintained that the new birth must always be preceded by agonies of repentance, and that only a regenerated theologian could teach theology, while the whole school shunned all common worldly acquaintance, and dedicated itself to the duty of the pulpit, and public worship. There thus arose a new form of justification by works. Its ecclesiæ in ecclesiæ also weakened the power and meaning of church organization. Through these extravagances a reaction movement arose at the beginning of the 18th century, one of the most distinguished leaders of which was Loescher, superintendent at Dresden.

As a distinct movement Pietism had run its course before the middle of the 18th century; by its very individualism it had helped to prepare the way for another great movement, the Illumination (Aufklärung), which was now to lead the world into new paths. Yet Pietism could claim to have contributed largely to the reform of the Church in the Netherlands the theatre, and public worship once more an affair of the heart and the life, and not merely of the intellect. It likewise vindicated a fresh the rights of the Christian laity in regard to their own beliefs and
the work of the Church, against the assumptions and despotism of an arrogant clergy. "It was," says Rudolf Sohm, "the last great surge of the waves of the ecclesiastical movement begun by the Reformation; it was the completion and the final form of the Protestantism created by the Reformation. Then came a time when another intellectual power took possession of the minds of men."

Some writers on the history of Pietism—e.g. Heppe and Ritschl—have included under it nearly all religious tendencies amongst Protestants of the last three centuries in the direction of the secondary cultivation of personal piety that then prevalent in the various established churches. Ritschl, too, treats Pietism as a retrograde movement of Christian life towards Catholicism. Some historians also speak of a later or modern Pietism, characterizing thereby a party in the German Church which was probably at first influenced by some remains of Spener's Pietism in Westphalia, on the Rhine, in Wurttemberg, and at Halle and Berlin. The party was chiefly distinguished by its opposition to an independent scientific study of theology, its principal theological leader being Hengstenberg; and its chief literary organ the Evangeligische Kirchenzeitung. The party, constituted the close of the wars with Holland.

Amongst older works on Pietism are J. G. Walch, Historische und theologische Einleitung in die Religionsstreitigkeiten der evangelisch-lutherischen Kirche (1730); A. Tholuck, Geschichte des Pietismus und des ersten Studiums der Aufklärung (1826); H. Schmitz, Die Geschichte des Pietismus und der Mystik in der reformirten Kirche (1879), which is sympathetic; A. Ritschl's Geschichte des Pietismus (3 vols., 1880-1886), which is hostile; and C. Sachse, Die Ursprung und Wesen des Pietismus (1884). See also Fr. Nolands's article in Theol. Stud. und Kritiken (1882), pp. 347-392; H. von Schubert, Outlines of Church History, ch. xxv. (Eng. trans., 1897); and Carol Miirbs's article, "Pietismus," in Hertzog-Hauck's Realencyclopädie für prot. Theologie u. Kirche, end of vol. xiv.

PIETRO DELLA VIGNA, or PIETRELLA VIGNE [PETRUS DE VINEAS or DE VINEIS] (c. 1190-1240), chancellor and secretary to the emperor Frederick II, was born at Capua in humble circumstances. He studied law at Padua, and through his classical education, his ability to speak Latin and his poetic gifts, he gained the favour of Frederick II, who made him his secretary, and afterwards judex magnae curiae, counsellor, governor of Apulia, prothonotary and chancellor. The emperor, "of whose heart he held the keys," as Dante says, sent him to Rome in 1232 and 1237 to negotiate with the Pope, and to Padua, in 1235, to obtain full recognition of his empire and protection, to England in 1234-1235 to arrange a marriage between Frederick and Isabella, sister of King Henry III. He proved a skilful and trustworthy diplomat, and he persistently defended the emperor against his traitors and against the pope's menaces. But at the Council of Lyons, which had been summoned by Pope Innocent IV., Pietro della Vigna entrusted the defence of his master to the celebrated jurist Taddeo of Suessa, who failed to condemn his predecessor. Frederick, whose suspicions had been awakened by the slanders of the envious, had him imprisoned and blinded without giving him a chance to rebuff his accusations. After his banishment and two years in prison at Pisa in 1249. The exact date, place and manner of his death are, however, subject to controversy, and Flaminio del Borgo states that it occurred in the church of S. Andrea, at Pisa, in 1256. The tragic fate of this man gave rise to many legends. The Guelfic tradition accuses Pietro della Vigna, as well as the emperor and the court, of heresy; it was even stated, probably without any foundation, that they were the authors of the famous work, De tribus impotentibus, wherein Moscov, Christ and Mahomet are blasphemed.

Pietro della Vigna was a man of great culture; he encouraged science and the fine arts, and contributed much to the welfare of the city. He has been called the father of the Reformation. He is the author of some delicate verse in the vernacular tongue, of which two comment and a sonnet are still extant. His letters, mostly written in the name of the emperor and published by Iselin (Epistolarium libri vii, 2 vols., Basel, 1740), contain much valuable information on the history and culture of the 13th century. A collection of the laws of Sicily, a Tractatus de postestate imperiali, and another treatise, "On Consolation," in the style of Boethius, are also attributed to him.

See Huillard-Bréholles, Vie et correspondance de Pierre de la Vigne (1864); Pressac, Pietreille de Vigne (Milan, 1880); Carasso and Iantelli, Pietreille de Vigne (Caserta, 1882); also FREDERICK II.

PIG (a word of obscure origin, connected with the Low Ger. and Dutt. word of the same meaning, bigge), a common name given to the domesticated swine of agricultural use. (For the zoology, see SWINE.)

British breeds of pigs are classified as black, white and red. In some places, notably Wales and Gloucester, a remnant of a spotted breed fingers; and a large proportion of common pigs, often parti-coloured, are mongrels. The white breeds are liable to sun-scald, and black pigs (like black men) are much better adapted than white to exposure in strong sunlight, conforming to the rule that animals in the tropics have black skins.

The Large Whites may have in the skin a few blue spots which grow white hair. The head is long, light in the jowl, and wide between the eyes, with long thin ears inclined slightly forward and fringed with long fine hair. The neck is long, but not coarse, the ribs are deep, the loin wide and level, the tail set high, and the legs straight and set well outside the carcass. The whole body, including the back of the neck, is covered with straight silky hair, which denotes quality and lean meat. Pigs of this breed are very prolific, and they may be grown to enormous weights—over 11 cwt. alive.

The Middle Whites are built on a smaller scale than the Large Whites. They are shorter in the heads and legs, and fuller at the jowl, thicker and more compact in the body. The sows are quite as prolific as those of the Large White breed, and, as their produce matures earlier, they are much in demand for breeding porkers.

The Small White pigs are beautifully proportioned. The head and legs are very short, and the body short, thick and wide; the jowl is heavy, the ears pricked, and the thin skin laden with long silky, wavy, but not curly, hair, whilst the tail is very fine. A deficiency of lean meat is a common characteristic of the breed, which is almost extinct.

The above three breeds were designated Yorkshire Whites, and are still so named at times. The Middle White, formed by crossing the large and the small breeds, is not so symmetrical as the parent stocks, and the type is not uniform.

The Lincolnshire Curly Coated or Boston pig is a local breed of great size and capacity for producing pork. It is very hardy and prolific, but somewhat coarse in the bone. It has an abundance of long curly hair, a short face and a straight nose, and the ears, not too long and heavy, fall over the face. It crosses well with the Large White, the Large Black and the Berkshire.

The Large Black breed, which vies with the Large White breed for size, and is probably its superior as a bacon pig, has only since 1800 received national show-yard recognition; but there is ample evidence that, with its characteristic whole black colour and curling hair, and lop ear, the Large Black existed in the south of England for generations. It has been continuously and carefully bred in Cornwall, Devon, Essex and Suffolk, and from these centres it has rapidly spread all over the country. Large Blacks are exceedingly docile, and the ears, hanging well forward over the eyes, contribute materially to a quietness of habit which renders them peculiarly adapted to field grazing. On account of their hardness and disposition to early maturity they have proved valuable for crossing purposes. The Large Black Pig Society was incorporated in 1809.

The Berkshire is a black pig with a pinkish skin, and a little white on the nose, forehead, pasterns, and tip to the tail. It has moderately short head with heavy jowl, a deep, compact carcase, and wide, low and well-developed hind-quarters, with heavy hams. The skin carries an abundance of fine hair. The Berkshire is an early-maturity breed which has been somewhat
ENGLISH BREEDS OF PIG, from photographs of F. Babbage. The comparative sizes of the animals are indicated by the scale of reproduction of the photographs.
inbred, and is not so hardy and prolific as most breeds. The
boars cross well with common stock. It merits the most credit
in raising the quality of Irish pigs. In America it is in the front
rank for numbers and quality as a lard-hog. There it often
grows to be a larger and finer animal than it is in England.
The Small Black or Black Suffolk was produced from the old
Essex pig by crossing with the Neapolitan. It resembles the
Small White, except that the skin is coal-black in colour, and
the coat of hair is not usually profuse. The Small Black, how-
over, is rather longer, and stands somewhat higher, whilst it
yields more lean meat than the Small White. It matures early
and is quick to fatten.
It is the second breed of the oldest breeds of pigs. It is hardy,
active and prolific, and nearly related to the wild boar. The
colour is red or chestnut, with at times darkish spots on the
skin. The head, body and legs are long, and the ribs deep and
broad. Originally a local breed in the districts around the Stafford-
shire town from which it takes its name, it is now extensively
bred, and highly valued as a bacon pig. (W. Fr.; R. W.)
In America nearly all the breeds may be classified as lard-
ghogs. Bacon-pigs fed on Indian corn degenerate into lard-
hogs, run down in size and become too small in the bone and
less prolific by inbreeding.
The Poland-China, the most popular breed in the United
States, is thus degenerating. It is a black pig like the Ber-
shire, but has shortlop-ears, a more pointed, straight nose, a
more compact body, and more white markings. It is a breed of
mixed blood, and is believed to have originated from the
"Big China" pig—a large white hog with sandy spots, taken
to Ohio in 1816, and blended with Irish graziers in 1839, and with
a breed known as Bayfields, as well as with Berkshires. In Iowa
the Berkshire is a combined lard and bacon pig in high favour.
The Duroc Jersey or Duroc, of a red or cherry-red colour—
not sandy or dark—is the most popular pig in Nebraska and
equal to any other in Iowa. It is a large prolific lard-hog, easily
making 300 lb in eight months. It has gained rapidly in popu-
larity since the beginning of this century, and is spreading to
other centres.
The Chester White, named from Chester county, Pennsyl-
vania, is one of the four leading breeds of lard-hogs in
America. It is of mixed origin and bears a strong family
resemblance to the Lincolnshire curly-coated pig. The early
English ancestors, the breed of which is not on record in
America, were most probably of Lincoln origin. The sow is
a prolific breeder and good mother, weighing, when mature but
not fat, 450 lb—the boar averaging 600 lb, and barrows at six
to eight months 350 lb. At Vermont Station, in a 127 days'
test, Chester Whites made a average gain of 10 lb in
12 days, 84 lb in 3 months, and they can gain fully 1 lb of live
weight for 3 lb of grain consumed.
Management. —The brood sow should be lengthy and of a prolific
strain, known to milk well. She is moderately fed and put to a
boar of her own age when large enough, i.e. seven to eight months
old. She remains in a state of oestrus for about three days, and
if not pregnant comes in heat again in three weeks. Breeding
swine, male and female, run most of their time at pasture and
receive a liberal allowance of green food or raw roots. The period
of gestation is sixteen weeks. Six to eight pigs are reared of the
first litter, and three of the second. Many brood sows are fastened
to greatest profit after the second or third litter. Two
fitters are produced in one year, as pigs are usually weaned at two
months old, and the sow will take the boar at from three days to
a week after the pigs are removed, according to condition. A
convenient sty to hold five or six pigs has a southern aspect, and
consists of a covered compartment and outer court, each 10 ft.
square. When the animals are fed pastured, the upper room is
elevated above the pigs' line. The labouring man's pig is
his bank, and is fed on scraps, small potatoes and waste products.
In connection with cheese dairies pigs are largely fed on sour
kitchen thickened with mixed meal produced from any one of the grain
or corn, which is thus degenerated. Many brood pigs are fed
for a few hours improves in digestibility, and a sprinkling of salt
is an improvement. Meal derived from leguminous seeds makes
the flesh firm and improves the quality. Fattening pigs are fed
three times a day and supplied with coal-ashes or a few handfuls
of earth. Of the fattened live weight of a pig 83% is butcher's
carcase, and 91% of the increase from 100 to 200 lb is carcass.
From 3 to 5 lb of meal consumed results in an increase of liv-
weight of live weight of a pig. A butcher's carcass.
and pig, which is the most common meat producer on a
farm. Concentrated and digestible foods give best results, a
pig has a small stomach. Fjord's Danish experiments show that
butcher's carcass is 36% of the carcass weight and the meal is the
importance of skins and ears is considerable. For skins
using skins and ears is 5 lb of 4 lb of potatoes.

PIGALLE, JEAN BAPTISTE (1744-1785), French sculptor, was
born in Paris on the 26th of January 1744. He was the
seven child of a carpenter. Although he failed to obtain the
grand prix, after a severe struggle he entered the Academy and
became one of the most popular sculptors of his day. His
earlier work, such as "Child with Cage" (model at Sèvres) and
"Mercury Fastening his Sandals" (Berlin, and lead cast in
Louvre), is less commonplace than that of his mature years,
but his nude statue of Voltaire, dated 1776 (Institut), and his
tombs of Comte d'Harcourt (c. 1764) (Notre Dame) and of
Marshall Saxe, completed in 1777 (Lutheran church, Strassburg),
are good specimens of French sculpture in the 18th century.
He died on 18th of August 1785.

Mélanges de littérature.
PIGUAULT-LEBRUN (PIGUAULT LE EPHINOV), CHARLES
ANTOINE GUILLAUME (1753-1833), French novelist, was born
at Calais (he is said to have traced his pedigree on the mother's
side to Eustache de Pierre) on the 8th of April 1753. His
youth was stormy. He twice carried off young ladies of some
position, and was in consequence twice imprisoned by lettre de
cahét. The first, a Miss Crawford, the daughter of an English
merchant whose office Pigault had entered, died almost
immediately after her elopement; the second, Mlle de Salens,
he married. He became a soldier in the Queen's Guards; then
a very unsuccessful actor, and a teacher of French. At
the breaking out of the great war he re-engaged and fought at
Valmy. He wrote more than twenty plays, and a large number of
novels, the first of which appeared in 1787. In his old age
he took to graver work, and executed an abridgment of French
history in eight volumes, besides some other work. His Œuvres
complètes were published in twenty volumes between 1822
and 1824, but much of his work is subsequent to this collection.
He died on the 24th of July 1835. The style of Pigault's novels
is insignificant, and their morality very far from severe.
As almost the latter of a kind of literature which later developed
greatly, Pigault-Lebrun deserves a certain place in literary
history. Among the most celebrated of his novels may be
mentioned L'Enfant du Carnaval (1792) and Angélique et Jeanne-
ton de la place Maubert (1799). His Citérat (2 vols., 1863),
a collection of quotations against Christianity, was forbidden
and yet seven times reprinted.
PIGEON (Fr. pigeon, Ital. piccione and pipione, Lat. pipio,
literally a nestling-bird that pipes or cries, out, "piper"—
the very name now in use among some pigeon-fanciers, though
"squeaker" in the more usual term). The name pigeon,
doubtless of Norman introduction as a polite term, seems to
bear much the same relation to dove as the word of Anglo-Saxon
"brun" has to sheep, beef to ox, veal to calf, and
pork to bacon; no sharp zoological distinction can be drawn
(see Dove) between dove and pigeon, and the collective members
of the group Columbidae are by ornithologists ordinarily called
pigeons. Perhaps the best-known species to which the latter
name is exclusively given in common speech1 is the wild pigeon
1 It may be observed that the "rock-pigeons" of Anglo-Indians
are Sand-grouse (q.v.), and the "cape pigeon" of sailors is a petrel
(q.v.).
or passenger pigeon of North America, *Ectopistes migratorius*, which is still found in many parts of Canada and the United States, though now almost extinct and never appearing in the countless numbers that it did of old, when a flock seen by A. Wilson was estimated to consist of more than 22,500 millions. The often-quoted descriptions given by him and J. J. Audubon of pigeon-haunts in the then "backwoods" of Kentucky, Ohio and Indiana need not here be reproduced. That of the latter was declared by C. Waterton to be a gross exaggeration; but the critic would certainly have changed his tone had he known that, some hundred and fifty years earlier, passenger-pigeons so swarmed and ravaged the colonists' crops near Montreal that a bishop of his own church was constrained to exercise them with holy water, as if they had been demons. 1 The passenger-pigeon is about the size of a common turtle-dove, but with a long, wedge-shaped tail. The male is of a dark slate-colour above, and purplish-bay beneath, the sides of the neck being enlivened by violet, green and gold. The female is drab-coloured above and dull white beneath, with only a slight trace of the brilliant neck-markings. 2 (See plate illustration under Dove.)

Among the multitudinous forms of pigeons very few can here be noticed. A species which might possibly repay the trouble of domestication is the wong-nong or white-leshed pigeon of Australia, *Leucosarcia picta*, a bird larger than the ring-dove, of a slaty-blue colour above and white beneath, streaked on the flanks with black. It is known to breed, though not very freely, in captivity, and is said to be excellent for the table. As regards flavour, the fruit-pigeons of the genus *Treron* (or *Vinago* of some authors) and its allies surpass all birds. These inhabit tropical Africa, India, and especially the Malay Archipelago; but the probability of domesticating any of them is very remote. Hardly less esteemed are the pigeons of the genus *Ptilopus* and its kindred forms, which have their home-quarters in the Pacific Islands, though some occur far to the westward and also in Australia. There may be mentioned the strange Nicobar pigeon, *Caloenas* (see plate illustration under Dove), an inhabitant of the Indian Archipelago, not less remarkable for the long lustrous hackles with which its neck is clothed than for the structure of its gizzard, which has been described by Sir W. H. Flower (Proc. Zool. Soc., 1860, p. 330), though this peculiarity is matched or even surpassed by that of the same organ in the *Phasornrhina gelaeta* of New Caledonia (Rev. de zoologie, 1861, p. 138) and in the *Carpophaga latrans* of Fiji. In this last the surface of the epithelial lining is beset by horny conical processes, adapted, it is believed, for crushing the very hard fruits of *Onocarpus vitisindia* on which the bird feeds (Proc. Zool. Soc., 1878, p. 102). The modern giants of the group, consisting of about half a dozen species of the genus *Columbia* and known as crowned pigeons (see plate illustration under Dove), belong to New Guinea and the neighbouring islands, and are conspicuous by their large size, beautiful filmy fan-shaped crest, and the reticulated instead of scutellated covering of their "tars."

A very distinct type of pigeon is that represented by *Didunculus dirigirostris*, the "Manu-men" of Samoa, still believed by some to be the next of kin to the Dodo (*p.p.*), but really presenting only a superficial resemblance in the shape of its bill to that extinct form, from which it differs osteologically quite as much as do other pigeons (Phil. Trans., 1860, p. 349). It remains to be seen whether the Papuan genus *Otidiphaps*, of which several species are now known, may not belong rather to the Didunculidae than to the true Columbidae.

Pigeons are now regarded as belonging to the Charadriiform or plover-like birds (see Brains) and are placed in the sub-order Columbidae, near the sand-grouse (*q.v.*). They are divided into three families, Didididae, which includes the Dodo (*p.p.*) and *Solitaire*, the Columbidae, which includes the doves and pigeons, and the Didunculidae, of which the curious tooth-billed pigeon, of Samoa is the only example. The body is always compact, and the bill has a soft skin or cere covering the nostrils. The pigeons are chiefly vegetable feeders and have a hard gizzard, and all drink much water; they perch, and have a note of the nature of a "coo." The nest is a rough platform or is in holes on the ground or on rocks. Many pigeons and the young, which are helpless when hatched, are fed by a secretion from the crop of the parents.

Pigeon-flying, the sport of racing homing-pigeons bred and trained for the purpose. It is of very recent date, although the use of birds as a means of carrying messages (see *Pigeon Post*) is of great antiquity. Belgium may be considered as par excellence the home of the sport, the first birds flown there probably coming from Holland. Long-distance flying began in 1818, with a match of 100 m., while in 1820 there was a race from Paris to Liége, and three years later the first race from London to Belgium. The sport is now a favourite one in Great Britain, the United States, France, and to a lesser degree, in some other countries, although nowhere attaining the general popularity which it enjoys in Belgium, where nearly every village has its *Société colombophile*, millions of pigeons being sent over the French border to be raced back. The annual Belgian *concours national*, a race of about 500 m. from Toulouse to Brussels, was inaugurated in 1881, in which the first regular races in Great Britain, from Exeter, Plymouth and Penzance to London, took place. The velocity attained at that time was about 1250 yds. per minute, but this was soon surpassed in the races of the London Columbrian Society, one of the winners in which attained a speed of 1836 yds. per minute.

The sport was introduced into the United States about the year 1875, although regular racing did not begin until 1878. Since then it has gained widespread popularity, the American record for old birds at 300 m. being 1848 yds. per minute and for young birds (yearlings) 1665 yds., while the distance record is 1000 m. The American "blue ribbon" championships are held at 100, 200, 300, 400, 500 and 600 m. The speed of homing-pigeons depends very greatly upon the state of the atmosphere. In the race from Montargis to Brussels in 1876 in bright and clear weather, all the prize-winners made the distance of 270 m. within three and one-quarter hours, while in the race of 200 m. on a thick and stormy day, thirty hours passed before the first bird arrived.

Training.—The loft should be on a commanding site. It is best made in the shape of a large room, suitably subdivided, protected from vermin, and provided with drinking troughs, rock salt and crushed mortar for the birds' use. It should be fitted with a sufficient number of nests about 2 ft. long, 20 in. in breadth and height. Arrangements should be made for allowing the pigeons to fly out daily for exercise; and they should be trained to re-enter the loft through bolting wires, which open inwards only, into a small chamber, to which an electric arrangement may be fitted so as to sound a bell and warn the owner of the arrival of a bird. The food of birds in training consists of vetch, beans, maize, peas, broken rice and uncooked, in various proportions. After the contest, in the months of May and June, the escape of the birds, when the climate and season of the year, the daily allowance for each bird being about 40 grammes weight. Young birds may be fed on rice in the husk and bread. They are called "squealers" for a week or two after birth, and then "squeakers" until about three months old. Each brood consists of two eggs, on which both parents sit in turn, the cock only for a few hours in the middle of the day. When the young are being brought up, only one of the parent birds is allowed in at a time, and the birds do not feed until their daily rations have been put away. When the young are out, the parent birds are let out in the morning, is sufficient. Training should commence in warm weather, when the bird is about four months old, and it continues until it has "tossed" it in a closed race course. It is then "tossed" into a closed race course, and "tossing" it at gradually increasing distances from its loft, with several days' interval of rest between the flights. The usual preliminary distances are 1, 2, 5, 10 and 15 or 20 m. These distances should be increased, and the birds should be trained to fly over some neighbouring city, in order that a bird may always have to fly in the same general direction during the season. About 100 m. may be expected of birds of the first season; they reach their full distances only about the fifth year. It is considered better to

1 *Voyages du Baron de la Hontan dans l'Amérique septentrionale*, i. 93, 94 (2nd ed., Amsterdam, 1709). In the first edition, published at the Hague in 1703, the passage, less explicit in details but to the same effect, is at p. 80. The author's letter, describing the circumstance, is at p. 699.

2 There are several records of the occurrence in Britain of this pigeon, but in most cases the birds noticed cannot be supposed to have found their own way hither. One, which was shot in Fife in 1855, may, however, have crossed the Atlantic unplanned by man.
train the young homing pigeons alone, so that they may become independent of the older birds. When thoroughly trained they may be flown over long distances about once a week. The Belgian fanciers generally divide their birds into two classes, one for breeding and the other for racing, though the latter are allowed to breed within certain limits. Some fanciers always choose birds with chicks in the nest for long journeys, claiming that they return faster with this method. The ring marked with the owner's name is slipped off the foot of the pigeon when only a few days old, and during its racing career the longer wing-feathers are stamped with the bird's records. At the start of a race the competing birds are kept together in a special start-box, which, when the time is over, is released. The homoer ascends rapidly in spirals until, apparently desiring some familiar landmark on the horizon, it will fly straight and swiftly towards it. As the birds enter their homolofts the time is stopped. It is not considered that they have got "home" until it has actually passed through the door of its loft.

**Pigeon Post.** The use of homing pigeons to carry messages is as old as Solomon, and the ancient Greeks, to whom the art of training the birds came probably from the Persians, conveyed the names of Olympic victors to their various cities by this means. Before the electric telegraph this method of communication had a considerable vogue amongst stockbrokers and financiers. The Dutch government established a civil and military pigeon system in Java and Sumatra early in the 19th century, the birds being obtained from Bagdad. Details of the employment of pigeons during the siege of Paris in 1870–71 will be found in the articles "Pigeon Post" and "Postal Service: the German and Indian Systems" in this Encyclopaedia. This led to a revival in the training of pigeons for military purposes. Numerous private societies were established for keeping pigeons of this class in all important European countries; and, in time, various governments established systems of communication for military purposes by pigeon post. When the possibility of using the birds between military fortresses had been thoroughly tested attention was turned to their use for naval purposes, to send messages between coast stations and ships at sea. They are also found of great use by news agencies and private individuals. Governments have in several countries established lofts of their own. Laws have been passed making the destruction of such pigeons a serious offence; premiums to stimulate efficiency have been offered to private societies, and rewards given for destruction of birds of prey. Pigeons have been used by newspapers to report yacht races, and some yachts have actually been fitted with lofts. It has also been found of great importance to establish registration of all birds. In order to hinder the efficiency of the systems of foreign countries, difficulties have been placed in the way of the importation of their birds for training, and in a few cases flocks have been specially trained to intercept the service in war-time, the Germans having set the example by employing hawks against the Paris pigeons in 1870–71. No satisfactory method of obliterating these birds seems to have been evolved, though the Chinese formerly provided their pigeons with whistles and bells to scare away birds of prey.

In view of the development of wireless telegraphy the modern tendency is to consider fortress warfare as the only sphere in which homing pigeons can be expected to render really valuable services. Consequently, the British Admiralty has discontinued its pigeon service, which had attained a high standard of efficiency, and other powers will no doubt follow the example. Nevertheless, large numbers of birds are, and will presumably continue to be, kept at the great inland fortresses of France, Germany and Russia.

**Pigeon-Shooting**, a form of sport consisting of shooting at live pigeons released from traps. The number of traps, which are six-sided boxes, falling flat open at the release of a spring, is usually five; these are arranged 5 yds. apart on the arc of a circle of which the shooter forms the centre. The distance (maximum) is 31 yds., handicapping being determined by shortening the distance. The five traps are each connected by wires with a case ("the puller"); a single string pulled by a man stationed at the side of the shooter works an arrangement of springs and cog-wheels in the "puller," and lets fall one of the traps; it is impossible to know beforehand which trap will be released. At a fixed distance from the centre of the traps is a boundary within which the birds must fall if they are to count to the shooter. This line varies in distance in the various clubs; the national Gun Club boundary being 65 yds., that of the Monaco Club being only 20 yds. The charge of shot allowed must not exceed 1½ oz. The best type of pigeon is the blue rock. From the start of the Hurlingham Club at Fulham in 1867 pigeon-shooting was a favourite sport there; it was, however, stopped in 1906. The principal pigeon-shooting centre in England is now at the National Gun Club grounds at Hendon. The great international competitions and sweeps take place at Monaco. An artificial bird of clay, now more usually of a composition of resins and pigments, is used for the live pigeon. These clay birds are also sprung from traps. This sport originated in the United States, where, under the name of "trap-shooting," or inanimate bird shooting, it is extremely popular. At first the traps invented threw the birds with too great regularity of curve; now the traps throw the birds at different and unknown angles, and the skill required is great. In clay-bird shooting the traps usually number fifteen, and are out of sight of the shooter. The Inanimate Bird Shooting Association in England was started in 1883.

**Pigments.** Pigments come from *Pigeon*, from *Pinguere*, to paint). It is convenient to distinguish between pigments and paints, the latter being prepared from the former by the addition of a vehicle or medium. Nor are pigments and dyes identical, although there are cases in which the same colouring matter which yields a dye or stain may give rise to a pigment. A pigment is, in fact, a substance which is insoluble in the vehicle with which it is mixed to make a paint, while a dye is soluble. Pigments exhibit various degrees of transparency and opacity, and ought to possess such qualities as these: ease in working, chemical indifference to each other and, generally, to the vehicles employed, also stability under exposure to light and air. As a rule, it is desirable that pigments should not be seriously affected in hue by the vehicle; at all events, whatever change does occur ought to admit of calculation. In the case of oil colours it should be remembered that a thorough drying of the paint is preferable to the formation of a surface-skin, and that a few pigments, notably white lead, possess properties conducing to this desirable result. It is scarcely necessary to add to these general observations concerning pigments that their artistic value depends primarily upon the nature and amount of the optical sensation which they are competent to produce.

Although the number of available pigments is great, the number of chemical elements which enter into their composition is not large. Very many röse-madder, for example, cannot be employed because they lack the properties of insolubility, inertia and stability. Pigments are drawn from various sources. Some are natural, some artificial; some are inorganic, some organic, some are elements, some mixtures, some compounds. It is not unusual to arrange them into two groups, substantive and adjective. Amongst the members of the former group such a pigment as vermilion, where each particle is homogeneous, may be cited as an example. Amongst the adjective pigments röse-madder may be named, for each particle consists of a colourless base on which a colouring matter (alizarin) has been thrown. Most of the inorganic pigments, whether natural or artificial, belong to the substantive group; while there are many organic pigments, notably those of artificial origin, which are of adjective character. The following table presents a summary classification of pigments according to their source or origin:—

<table>

A variety of processes are in use in order to fit natural coloured substances for employment as pigments. The first step is,
in many cases, to select, or "pick over," the raw material, rejecting whatever impurities may weaken or injure the character of the product. It is occasionally necessary to treat the finely-ground substance with water by the method of elutriation or washing-over; the wash-waters will then deposit, on standing, various grades of the coloured body required. With rare exceptions native pigments need careful grinding, either by means of a muller on a slab or by edge rollers, or horizontal mill-stones, or special machines. The substance is usually ground in spirits of turpentine, or alcohol, or water; oil-paints are of course finally ground in a drying-oil, such as linseed oil or poppy oil; water-colours require gum-water, or gum-water and glycerin if they are to be "moist" paints. In the case of all pigments, whether mineral or organic, whether natural or artificial, it is of the highest importance to make sure that they are free from saline matters soluble in water. Such salts are removed by thorough washing with distilled water. A treatment of this kind is essential in the case of a large number of pigments formed by chemical reactions in the "wet way." Characteristic examples are furnished by Prussian blue, viridian and lakes. Sometimes it is necessary to remove dangerous impurities by solvents other than water, such as carbon bisulphide, which is used to extract free sulphur from cadmium yellow. Mention may here be made of another kind of preparative treatment which is adopted with some pigments: they are subjected to the action of heat—moderate in some cases, strong in others. Thus, a few substances, such as ivory black and yellow ochre, which in ordinary circumstances contain much non-essential moisture, before they are ground in oil may with advantage be gently dried at a temperature not above that of boiling water. Again, there are pigments, such as Prussian brown, light red and burnt sienna, which owe their hues to a process of actual calcination, the first of these being thus made from Prussian blue, the second from yellow ochre, and the third from raw sienna. The pigments known as burnt carmine and burnt madder are prepared at a much lower temperature, and ought to be described as roasted rather than as burnt.

Preparation.

Adulteration.

It is not so unusual to find that a costly substance has received an admixture of something cheaper, and that an inferior grade of a genuine pigment has had its lustre excalated or enhanced by some unlawful or dangerous admixture. Thus vermillion is adulterated with red lead, with red antimony sulphide, or with baryta white and lead sulphate, and then the hue of the mixture is restored to the proper pitch by the introduction of the powerful but fugitive colouring matter eosin. Amongst other adulterations which may be named here are the addition of chrome-yellow (lead chromate) to yellow ochre, of green ultramarine to terre verte, and of indigo to ivory black; this last mixture being a substitute for vine-black, the natural blue-black. The detection of the above-named sophistications is by no means difficult even in the grossly calcined and manipulated, with chemical manipulation, but it needs a trained analyst whose knowledge of pigments is required. If we are dealing with an oil-colour, the first step is to remove the oil by means of a solvent, such, for example, as ether. The residual pigment is then allowed to dry, and the dry powder submitted to the appropriate physical and chemical tests. Thus a suspected vermillion, having been freed from oil, is heated in a small hard glass bulb-tube; it should prove practically volatile, leaving a mere trace of residue. In this particular case the presence of a red hue in the ether-extract affords evidence of adulteration with an organic colouring matter, such as eosin. Then, again, we may detect the presence in yellow ochre of lead chromate by putting a little sulphured hydrogen water and dilute hydrochloric acid upon one portion of the dry pigment, and boiling another portion with dilute sulphuric acid and some alcohol: in the former experiment blackening will occur, in the latter the liquid part of the mixture will acquire a greenish tint. So also green ultramarine may be recognized in adulterated terre verte by the addition of dilute hydrochloric acid, which destroys the colour of the adulterant and causes an abundant evolution of the evil-smelling sulphured hydrogen. Moreover, nothing is easier than the recognition of indigo in vine or charcoal-black, for the dry powder, heated in a glass tube, gives off purple vapours of indigo, which condense in the cooler part of the tube into a blackish sublimate.

A word must be said here as to the adulteration of white lead, and the examination necessary for the detection of this most important pigment. The best variety of white lead or flake white contains two molecules of lead carbonate to one of lead hydrate, and is wholly soluble in dilute nitric acid, while barium sulphate, its most frequent adulterant, is wholly insoluble. China-clay and lead sulphate will also remain undissolved; but whitening or chalk cannot be detected in this way—indeed, the thorough examination of white lead, not only for sophistications but also for correspondence with the best type in composition, cannot be carried out save by a skilled chemist.

Pigments may be classified on two systems: (1) based on the chemical composition; (2) based on the colour. On the first system pigments fall into nine groups, seven of which are fairly well defined, but the eighth and ninth have a somewhat miscellaneous character.

The groups of elements, oxides, sulphides, hydrates, carbonates and silicates present this characteristic, namely, that each member of any one group is without action upon the other members of the group; any two or more may therefore be mixed together without fear of mutual injury. The same statement may be made with reference to the various inorganic salts of Group VIII. and to the organic compounds of Group IX., although in this large final group there are two pigments containing copper (verdigris and emerald green) which must be regarded with suspicion. The inertness of the members of the same group towards each other may be explained in the majority of cases by the following consideration. An oxide does not act upon an oxide, nor does a sulphide affect a sulphide, because all the pigment oxides have taken up their full complement of oxygen, and can neither give nor lose this element to similar oxides; so also with sulphur in the sulphides. A few details regarding the several members of the nine groups are now offered:

Group I. Elements.—All the black pigments in ordinary use—ivory black, lamp black, charcoal black, Indian ink, and graphite, often termed black lead and plumago—consist of or contain carbon. A pigment not liable to change in colour is lead sulphonate, silver, gold, silver, aluminium and platinum, belonging here; of these, silver alone is easily susceptible of change, tarnishing by combination with sulphur.

Group II. Oxides.—The oxides have generally been formed at a high temperature and are not easily amenable to physical or chemical change; they are, moreover, not liable to affect other pigments, being practically inert, red lead only being an exception. The oxides include zinc white, green chromium oxide, burnt umber (a mixture of iron and manganese oxide), cobalt green (CO₃₉₄ZnO), cobalt blue (CO₇M₉O₉), cueruleum (CO₃₂SnO₃), Venetian red, light red, indian red and burnt sienna (all chiefly composed of ferric oxide) and red lead (Pb₃O₄).

Group III. Sulphides.—Some of the members of this group are liable to contain free sulphur, and some may give up this element to the artistic base. Cadmium sulphide, for example, is a common pigment. Amongst others are blackmer emerald green, producing copper sulphide. Another pigment of this group, vermillion, is prone to a molecular change whereby the red form passes into the black variety. This change, frequent in water-colour drawings, is scarcely observable in works painted in oil. The sulphides comprise cadmium yellow (CdS), orpiment (As₂S₃), realgar (As₂S₃) antimony red (Sb₂S₃) and lead sulphide (PbS). It is convenient to give places in the same group to the various kinds of molybdenum blue and native, for in all of them a part of the sulphur present occurs in the form of a sulphide. It may be stated that the sulphides of arsenic only just naturally dangerous and changeable pigments not suited for artistic painting.

Group IV. Hydrates or Hydroxides.—Several native earths belong here, notably yellow ochre, raw umber, raw sienna and such like. Of these, the ochres are the result of the combination of the hydrates and oxides of iron and of manganese, but the presence of a colourless body such as white clay or barium sulphate is usual with the paler pigments. A false yellow ochre from Cyprus is really a basic ferric sulphate, and does not properly belong to this
group. Besides the yellow and brown pigments, there is a magni-
cent deep green pigment in this group, known as emerald oxide of
chromium or viridian. The blue copper preparation which goes
upwards is known as Prussian blue, yellow, and green. It is a
pigment, is also essentially a hydrate, though by no means pure.
It should be stated that all the earthy or native concentrates belong
to the silicates, and in particular, namely, hygroscopic
loosely-attached and not constitutional. But two others may have the
reduction in the amount of the hygroscopic moisture by means of
a current of dry air or a gentle warmth often improves the hue and
strength of these pigments.

GROUP V. Carbonates. There is but one really important
member of this group, namely, the old and typical variety of white
(2PbCO₃·Pb(OH)₂). Like green verditer (CaCO₃·Cu(NO₃)₂), and like lead verditer (PbCO₃·H₂O), a carbonate. Purifies,
chalk or whitening (CaCO₃) belongs here also.

GROUP VI. Silicates. Terre verte, which is a natural green
oxygen compound, is a silicate of iron, potassium and magnesium,
and one other silicate, a silicate of cobalt and potassium, constitute
this small group. However, some of the ochreous earths contain silicates of iron, manganese and aluminium, as well as hydrates of the two druser metals, and so
have some claim to be ranked with the silicates.

GROUP VII. Chromates. These salts are rich in oxygen. When
in contact with some of the more alterable organic pigments belong-
ing. In this group, the chromates may lose oxygen, acquiring a
somewhat greenish or greyish hue, owing to the formation of the
lower or green oxide of chromium. The chromates cannot be
trusted as pigments. The yellow chromates, those of barium,
strontium, or lead, are relatively inert, or almost so, and are used in
the general formulae: M’₂CrO₄; chrome red is basic, and is Pb₂CrO₄.

GROUP VIII. Various Inorganic Salts. This group is intended to
include all the pigments, inorganic salts, are solitarily, or almost so,
examples of varieties of classes of salts. There are, for exam-
ple, nitrate, auriculoin (K₂Co₃(N₃)₄), associated with one or more molecules of water, called sometimes cobalt yellow; one antimonite, that
of lead, or lead yellow; and one arsenite, that of arsenic, known as tungsten green; a metaphosphate of manganese, which
goes under the name of Nürnberg or manganese violet; and several mixed cobalt compounds containing arsenates and phosphates of that metal, and represented by cobalt violet, and cobalt red.

Two sulphates also belong here, namely, baryta white (BaSO₄)
and lead sulphate (PbSO₄); also Schweinfurt green, a basic copper
arsenite. It is obvious that of the members of so miscellaneous
a group, all the general characteristics of the salts can be
stated. But it may be stated that the two sulphates, the tungstate and the cobalt compounds are practically inert and unalterable, while the
complex compounds are subject to oxidation and to the
action of sulphur and of phosphates. The cobaltinitrite, auriculoin, cannot
be safely mixed with some of the organic pigments belonging to
the next and last group.

GROUP IX. Compounds. Most of the members of this large
and unwieldy group of pigments possess this character in
common, proneness to oxidation and consequent deterioration in
the presence of light, moisture and air. Such oxidation is acceler-
ated by the meeting of those high and certain requirements given
by other groups, such as the chromates of Group VII and auriculoin
of Group VIII, this action being particularly marked in the case
of the yellow lakes, the cochineal lakes and indigo. There are no
pigments in this group that are of any importance, and we
may, therefore, pass over it.

Both the blue-green and the green varieties being basic copper
acetates—and the pigment known in England as emerald-green,
which is a basic cupric acetate compound. These copper pigments
present the usual sensitiveness to the attack of sulphur which dis-
tinguishes compounds of this metal, and cannot therefore be safely
mixed with the members of Group III, and more particularly with
the cadmium colours. About nine members of Group IX may be
regarded as substantive pigments. These include Indian yellow
(magnesium and calcium euxanthes), gamboge, sap green,
indigo, Prussian blue, bitumen or asphalt, bistre, sepiolite, and
the bitumen of pitch. Indian yellow and gamboge contain the
same acid that is present in the linden tree, and are of
importance. Amongst the various pigments which may be regarded
as primary pigments that yield secondary pigments, there are
a great variety of lakes where different kinds of colouring
matters of more or less acid character have been thrown upon a
base, generally of colourless aluminium hydrate, aluminium phos-
phate, stannous hydrate, stannous oxide, barata or lime; sometimes
coloured bases containing such metals as copper, chromium, manganese or iron are introduced in small quantities. The colour-
ing matters used are both natural and artificial. For example,
Indian lake from the resinous exudation produced in certain trees by the attacks of Coccos lacca; carmine, crimson and purple lake, from the colouring matter obtained from the触媒 leucomaena acalcula and other leucomaenas; lakes, from the alizarin and allied bodies derived from the root of
the ordinary madder plant Rubia tinctorum; and yellow lakes, from quercitin bark (Quercus tinctoria), and from Persian and Avignon
beech, and from several other works. There are also lakes
from alkanet root, archial, Brazil wood, and red sanders wood are
of very small interest and value. The same judgment may be
pronounced upon the large number of artificial lakes which owe
their colours to coal-tar derivatives, with the single exception of
the important class of pigments obtained from artificial alizarin,
and from its congeners and derivatives. Of these, alizarin (α,β)
which, in its purest state and associated with a little sodium
and a little strontium, yields those pigments which are pink or rosy
hue. When purpurin and its isolomers, anthrapurpurin and the like,
are present, the red hue is more pronounced, and may even tend
towards a golden colour, or, when some copper or iron or manganese
is introduced, a yellow is produced. But some of these lakes,
crimson so sold as not made from alizarin itself, but from the sulphonic acids of alizarin. These lakes present a wide range of
colours. Another derivative of alizarin, known as β-nitro-alizarin,
can be mixed with such bases as cobalt blue, or copper, or copper
alginate, to which such names as pure orange, orange madder and margiold have been applied.

Stability. Some notion of the relative stability of pigments will
have been derived from the remarks already made under
"Classification." But as permanence is of no less importance than
chromatic quality in the case of pigments used in the fine
art of painting, to which the present article is mainly devoted,
there will be much more discussion concerning certain selected pigments may
profitably be given here. Beginning with white pigments, these
time may be named as useful; white lead, Freeman's white, zinc
white. As an oil-colour, white lead of the old type is generally
the best to use, but among water-colours its place must be
taken by zinc white in the condensed form known as Chinese
white. Zinc white, in spite of the qualities which recommend
its use in oil, namely, the fact of its being not only unaffected by
sulphur, but colourless and non-poisonous, lacks toughness as an
oil-paint, and has a tendency to scale. Freeman's white,
which consists essentially of lead sulphite, is the best substitute
for white lead yet devised. The small percentages of zinc white
and baryta white which it contains are not to be regarded as
 adulterations, for they greatly increase its body, and though of
less specific gravity than lead sulphate, actually raise the weight
per cubic foot of the dry pigment. Out of a dozen or more
familiar yellow paints, a selection may be made of these six:
yellow ochre, raw sienna, mars orange, cadmium yellow, auriculoin
and baryta yellow. Concerning two of these, cadmium yellow
and auriculoin, the following observations may be set down.
Cadmium sulphide, CdS, exists in two forms, which in some
measure correspond to the two modifications of mercuric and
antimonious sulphides. One of these forms is yellow and the
other reddish orange. When sulphuric acid, hydrogen is sent
into a weak, cold, and neutral solution of cadmium salt, the
sulphide which separates is pale and yellow—the orange variety
is obtained from a strong, hot, and acid solution. The pale
variety is more prone to change than the darker one; but as oil
paints are only faintly affected by temperature and moisture, these products are pure. The value of auriculoin as a pigment depends much
upon its mode of preparation. A new variety of bright yellow
hue was described by Adie and Wood in 1890, and is represented
by the formula K₂NaCo(NO₃)₄, H₂O. Of red pigments, six claim special
mention. These are vermilion, light red, Venetian red, Indian
red, red ochre, and the red lakes derived from madder
or alizarin. Vermilion is stable in oils, but as water-colour
paint is prone to change, under exposure to strong light,
into the black modification of mercuric sulphide. The iron-reds
named above, whether natural or artificial, are quite permanent,
but so much cannot be said of the various madder-paints. They
are affected by temperature, and are not durable under exposure
of red organic pigments, and are absolutely necessary to the artist.
It must be noted that those madder and alizarin lakes which
contain an element of yellow and brown are less stable than
those of a crimson hue. Five green pigments may be recom-
manded, namely, viridian, or the emerald oxide of chromium,
the ordinary green oxide, cobalt green, green ultramarine,
and terre verte. Except for minor decorative work, where perman-
ence is of secondary moment, one is obliged to exclude from the
palette emerald green, green verditer, verdigris, sap-green,
and the numerous preparations which owe their colour to mixtures
of Prussian blue and chrome yellow, and are sold under the names
of Berlin green, Hamburg green, and Prague green. The
remaining green pigments are all artificial.

All these pigments usually contain much barium sulphate.
Similarly, amongst blue pigments, ultramarine, cobalt blue
and coeruleum may be retained, while small, indigo and all
copper blues should be rejected. Prussian blue, or the mixture of this pigment with a white base which is usually called Antwerp blue, can scarcely be spared, but care should be taken to choose a sample containing no potassium compounds. Coeruleum, which may be described as cobalt stannate presents the peculiarity of appearing a greenish blue in artificial light, not a purplish blue like that of ordinary cobalt blue. Cobalt violet is a sound pigment; but a magnesium metaphosphate or Nürnberg violet is not to be bought. Modern India, an artificially prepared ferric oxide, is dull in hue but permanent. Passing to other pigments, it is matter for regret that there are no permanent colours possessing the artistic capacities of asphalt, madder brown, and the old bituminous Vandyke brown. Capprugh brown, burnt sienna, and raw and burntumber may be employed safely. Little need be said as to the selection of black pigments, for all are permanent. The soot from burning acetylene, which has recently been introduced, forms a black pigment of remarkable intensity.

Uses.—Hitherto pigments have been considered chiefly in relation to the requirements of the painter of pictures. In many merely decorative arts, such as the manufacture of wall-papers and the painting of woodwork and of iron, the pigments available are in one direction, that of cost, more restricted, but, on the other hand, many alterable or weak pigments are commonly employed. In paints intended for the protection of iron-work, the nature of the pigment introduced is a matter of great moment, for red lead, zinc white and white lead are found to exert a strong protective influence, which is not observed in the case of the vast majority of pigments. There are a number of other uses besides those just named for which special pigments, or, more precisely, special paints, are employed. Amongst such preparations may be named luminous paints, anti-fouling paints, metallic paints, damp-proof paints, and asbestos and other fire-proof paints.

**PIGOT, GEORGE, Baron (1719-1777), English governor of Madras, was born on the 4th of March 1719 and entered at the service of the East India Company in 1736; after nineteen years he became governor and commander-in-chief of Madras in 1755. Having defended this place against the French in 1756 and occupied Pondicherry on behalf of the company, he resigned his office in November 1763 and returned to England, being made a baronet in 1764. In the following year he obtained a seat in parliament, and he retained his until his death; in 1766 he was created an Irish peer as Baron Pigot. Returning to India in 1775 to occupy his former position at Madras, Pigot was at once involved in a fierce quarrel with the majority of his council, which arose out of the proposed restoration of the rajah of Tanjore. The governor was arrested by order of his opponents, and was still a prisoner when he died on the 11th of May 1777. Meanwhile the Pigot censure was carried by the court of directors in England and the order for his restoration was followed immediately by another for his recall. This happened about a month after his death, but before the news had reached England. In 1779 the matter was discussed in parliament, and four of those who were responsible for his arrest were tried and were fined £1000 each. Pigot, who left several illegitimate children, was never married, and his barony became extinct.

Two of the governor's brothers were men of repute. Sir Robert Pigot (1721-1756), who succeeded to the baronetcy, commanded his regiment (the 78th) in the battles of Lexington and Dunker Hill during the War of American Independence. He became a lieutenant-general in 1782. The other brother, Hugh Pigot (c. 1721-1772), was still a prisoner when he died on the 11th of May 1777. Meanwhile the Pigot censure was carried by the court of directors in England and the order for his restoration was followed immediately by another for his recall. This happened about a month after his death, but before the news had reached England. In 1779 the matter was discussed in parliament, and four of those who were responsible for his arrest were tried and were fined £1000 each. Pigot, who left several illegitimate children, was never married, and his barony became extinct.

During a mutiny in September 1797 while in command of the "Hermione." **PIG-STICKING, or Hog-Hunting, the chase of the wild boar, as a sport, on horseback with the spear. The chase on foot is common among ancient peoples, and in central Europe has lasted to the present day, although, on account of the introduction of fire-arms, the spear has gradually become an auxiliary weapon, used to give the coup de grâce to a wounded animal. The modern sport is the direct descendant of bear-spearling which was popular in Bengal until the beginning of the 19th century, when the bears had become so scarce that wild pigs were substituted as the quarry. The weapon used by the Bengalese was a short, heavy, broad-bladed javelin. British officers introduced the spear or lance and this has become the recognized method of hunting wild pigs in India. The season for hunting in northern India, the present headquarters of the sport, is from February to July. The best horses should be quick and not too big. Two kinds of weapon are used. The long, or underhand, spear, weighing from two to three pounds, has a light, tough bamboo shaft, from seven to eight feet long, armed with a small steel head of varying shape. This spear is held in the hand about two-thirds the distance from the point, with the knuckles turned down and the thumb along the shaft. The short, or jobbing, spear is from six to seven and a half feet long, and somewhat heavier than the longer weapon. It is grasped near the butt, with the thumb up. Although easier to handle in the jungle, it permits the nearer approach of the boar and is therefore more dangerous to man and mount. The boar arrived at the bush-grown or marshland haunt of the pigs, the quarry is "reared," i.e. chased out of its cover, by a long line of beaters, usually under the command of a mounted shikari. Sometimes dogs and gun loaded with small shot are used to induce an animal to break cover. The mounted sportsmen, placed on the edge of the cover, attack the pig as soon as it appears, the honour of "first spear," or "spear of honour," i.e. the thrust that first draws blood, being much coveted. As a startled or angry wild boar is a fast runner and a desperate fighter the pig-sticker must possess a good eye, a steady hand, a firm seat, a cool head and a courageous heart. For these reasons the military authorities encourage the sport, which is for the most part carried on by the tent clubs of the larger Indian stations.

**PIKE, ZEBULON MONTGOMERY (1777-1813), American explorer and soldier, was born in Lamberton (now a part of Trenton), New Jersey, on the 5th of January 1779, son of Zebulon Pike (1751-1834), an officer in the American army. He entered his father's company as a cadet but 1794, and became an ensign (or second lieutenant) in 1799 and first lieutenant in the same year. On the 6th of August 1805 he started with twenty men from St Louis to explore the head-water of the Mississippi. At Prairie du Chien he met some Chippewa chiefs and induced them to expel the whisky-traders among them and to make peace with the Sioux; at the Falls of St Anthony (Sept. 23) he built a tract 9 m. square at the mouth of the St Croix for a fort; and at Little Falls (in the middle of October) he built a stockade, where he left seven men. He reached Leech Lake ("Lake La Sang Sue"), which he called "the main source of the Mississippi," on the 1st of February 1806; went 30 m. farther in Cass Lake ("Red Cedar") and, after working against British influences among the Indians, turned back, and went down the Mississippi from Dean Creek to St Louis, arriving on the 5th of April. In 1806 he was
ordered to restore to their homes 50 Osages, redeemed by the United States government from Potawatami, and to explore the country. He started on the 15th of July; and went north along the Missouri and the Osage into the present state of Kansas and probably to the Republican river in the south of the present Nebraska, where on the 29th of September he held a grand council of the Pawnees. Then (early in October), turning nearly south, he marched to the Arkansas river, which he reached on the 14th of October, and up which (after the 28th with only 16 men) he went to the Royal Gorge (Dec. 7), having first seen the mountain called in his honour Pike's Peak on the 23rd of November; and then went north-west, probably up Oil Creek from Cañon City. In searching for the Red river he came to the South Platte, marched through South Park, left it by Trout Creek pass, struck over to the Arkansas, which he thought was the Red River for which he was searching, and, going south and south-west, came to the Rio Grande del Norte (about where Alamosa, Conejos county, Colorado, is now) on the 30th of January 1807. There on the 26th of February he and a small number of his men were taken prisoners by Spanish authorities, who sent him first to Santa Fé, then to Chihuahua to General Salcedo, and by a roundabout way to the American frontier, where he was released on the 1st of July 1807. He was promoted captain (August 1806), major (May 1808), lieutenant-colonel (Dec. 1809) and colonel (July 1812). In 1808 he tried in vain to get an appropriation from Congress for himself and his men. He was military agent in New Orleans in 1808-1810, was deputy quartermaster-general in April-July 1812, and was in active service in the War of 1812 as adjutant and inspector-general in the campaign against York (now Toronto), Canada, and in the attack on York on the 27th of April 1813 was in immediate command of the troops in action and was killed by a piece of rock which fell on him when the British garrison in its retreat set fire to the magazine.

His Account of an Expedition to the Sources of the Mississippi and through the Western Parts of Louisiana and a Tour through the Interior Parts of New Spain was published at Philadelphia in 1810; was reprinted and rearranged in London in 1811; and was published in a French version in Paris in 1812, and a Dutch version at Amsterdam in 1812-1813. The standard edition with memoir and notes by Elliott Coues was published in three volumes in New York in 1895. Some of Pike's papers taken from him in Mexico are now in the Mexican archives (Seccion de Asuntos Inter-nacionales caza 1817-1824), and the more important were published by H. E. Bolton in the American Historical Review, (1907-1908), xiii. 798-827. See the sketch by Henry Whiting in vol. v., series 2, of Jared Sparks's Library of American Biography.

PIKE, fresh-water fishes generally distributed over the rivers and lakes of Europe, northern Asia, and North America, and forming a small family (Esocidae) of soft-rayed fishes. They are readily recognized by their elatate compressed body covered with small scales, a long head, long and spatulate snout, and very large mouth armed with strong and long teeth in the jaws and broad bands of smaller teeth on the palate and tongue. The teeth point backwards or can be depressed so as to offer no obstruction to any object entering the gape, but prevent its withdrawal in the opposite direction. The dorsal and anal fins are placed far back on the tail, thus greatly increasing the propelling power of the fish, and, although pike are bad swimmers and lead rather a sedentary than a roving life, they are excelled by no other fresh-water fish in rapidity of motion when, by a single stroke of the tail, they dash upon their prey or dart out of reach of danger. In the Old World one species only is known (Esox lucius), which prefers lakes and sluggish reaches to strong currents or agitated waters. Its eastward range in northern Asia is not known; it extends into Lapland in the north and into central Italy and the vicinity of Constantinople in the south, but is absent in the Iberian Peninsula. The European species occurs also in North America, and is common in the eastern United States southwards to northern Ohio. But North America is tenanted by other species of pike besides, of which the largest is the muskellunge or maskinonge of the Great Lakes (Esox nubiolor); it commonly attains to the large size which is exceptionally recorded of Esox lucius. The other American pike are of smaller size, and generally named "pickeral", but opinions as to the distinction of the species differ. The North American ichthyologists. The European pike, like its brethren, is the most voracious of fresh-water fishes; it probably exceeds the shark, to which it has been compared by many writers, in the relative quantity of food it consumes. Large specimens will seize rats or water-voles, and are said to attack even foxes and small dogs. Individuals of from 40 lb to 50 lb are not scarce, but captures of much larger ones are on record. Pike are wholesome food, and much esteemed in inland countries—the smaller (of 20 to 24 in. in length) being preferred to the larger individuals. They are prolific, and not easily exterminated, in a water in which they have been once allowed to spawn. According to season and climate they spawn in April or May, and sometimes as early as February.

PIKE, a word which, with its collateral forms "pick" and "peak," has as its basic meaning that of anything pointed or tapering to a point. The ultimate etymology is much disputed, and the interrelation of the collaterals is very confused. In Old English there are two forms (píc, one with a long and the other with a short vowel, which give "pike" and "pick" respectively. The first form gave in the 15th century the variant "peak," first with reference to the peaked shoes then fashionable, peský schone. In Romantic languages are found Fr. pic, Span. pico, Ital. picare, to pierce, &c. There are also similar words in Welsh, Cornish and Breton. The Scandinavian forms, e.g. Swed. and Nor. pík, are probably taken from English. While some authorities take the Celtic as the original, others look to Latin for the source. Here the woodpecker, picus, is referred to, or more probably the root seen in spica, ear of corn, and spína, prickle (English spike, spine). The current differentiation in meanings attaching to pike, pick and peak are more or less clearly marked, though in dialects they may vary. (1) Pike: Apart from the use as the name of the fish (see above), probably a shortened form of pike-fish, from its sharp, pointed nose; and a weapon of the common use at the knee, given earlier to the great iron headed spear known as "pike," and brought to the attention of the foot-soldier till the introduction of the bayonet (see SPÁR and BAYOYET), and for a hill with a pointed summit, appearing chiefly in the names of such hills in Cumberland, Westmorland and North West Lancashire. It may be noticed that the proverbial expression "plain as a pike-staff" appears originally as "plain as a pack-staff," the flat plain sided staff on which a pedlar carried and rested his pack. The use of "pike" for a highway, a toll-gate, &c., is merely short for "turnpike." (2) Pick: As a substantive this form is chiefly used of the common tool of the navy and the miner, consisting of a curved double-ended hand set at right angles to the handle, one end being squared with a chisel edge, the other pointed, and used for loosening and breaking hard masses of earth, coal, &c. (see TOOLS). The other name for this tool, "pickaxe," is a corruption of the earlier pikýos, Fr. picóis, M. Lat. picósum, formed from Fr. pic, the termination being adapted to the familiar English "axe." The sense-development of the verb "to pick" is not very clear, but the following meanings give the probable line: to dig into anything like a bird with its beak, in order to extract or remove something, to gather, pluck, hence to select, choose. (3) Peak: The chief uses are for the front of a cap or hat projecting sharply over the eyes, for the part of a ship's...
PIKE-PERCH—Pilate

hold where it narrows towards the bow, the fore-peak, or towards the stern, the after-peak, for the top corner of a sail extended by a gaff, or for the projecting end of the gaff itself, and for a pointed or conical top of a hill or mountain. The name of the high table-land district in Derbyshire is not to be connected with this word, but probably retains the name of an old English demon, Peac (see Peak, Tne).

PIKE-PERCH (Lucioperca), fresh-water fishes closely allied to the perch, but with strong canine teeth standing between the smaller teeth of the jaws and palate. They resemble the pike in their elongate body and head, and they are also most dangerous enemies to other fresh-water fishes, though they compensate for their destructiveness by the excellent flavour of their flesh. In Europe two species occur, the more celebrated being the "Zander" of North Germany or "Schiel" of the Danube (Lucioperca sandra); strange to say, it is absent in the system of the Rhine. It prefers the quiet waters of large rivers and clear deep lakes, in which it reaches a weight of 25 lb or 30 lb. The second (Lucioperca wolgensis) is limited to rivers in southern Russia and Hungary. In North America several pike-perches have been described, but in the most recent works only two are distinguished, viz. Lucioperca americana, which grows to a weight of 29 lb, and the much smaller Lucioperca canadensis; both are abundant in the Canadian lakes and upper Mississippi, and the latter also in the Ohio.

PIKE'S PEAK, a famous peak of the Rampart range of the Rocky Mountains in El Paso county, Colorado, U.S.A., about 6 m. W. of Colorado Springs. Though surpassed in altitude (14,108 ft.) by many summits in the state, no other is so well known. The commanding appearance of the peak is very fine. To the south are Cameron Cone (10,685 ft.), Mt Sachett, Mt Bald (13,974), Mt Rosa (11,427), and Mt Cheyenne (9,907). From the summit the magnificent Sangre de Cristo range is in the foreground, while on a clear day not only its southernmost summit, Blanca Peak (14,390 ft.), is visible, but also the Spanish Peaks (14,798 and 15,625 ft.) 100 m. to the south, and Long's Peak to the north, and between them Mt Lincoln, Gray's Peak and other giants. At the base of the mountain are Manitou and Colorado Springs, whence tourists can make the ascent of the peak (in summer safe and relatively simple) on horseback or by a cog-railway, 8-75 m. long (opened in 1891), which makes a total ascent of 8100 ft. (maximum gradient 1 in 4) to the summit. In 1903 a powerful searchlight was erected on the summit. Pike's Peak was discovered in November 1806 by Lieut. Zebulon M. Pike. He attempted to scale it, but took the wrong path and found himself at the summit of Cheyenne Mountain. He pronounced the mountain unclimbable. In 1819 it was successfully climbed by the exploring party of Major S. H. Long.

PILASTER (Fr. pilastre, med. Lat. pilastrum, from pilis, a pillar), in architecture, an engaged pier projecting slightly from the wall, and employed to divide up and decorate a wall surface or to serve as respond to a column. One of the earliest examples (c. 100 B.C.) exists in the propylaea at Priene in Asia Minor, where it tapers towards the top. Pilasters have bases and capitals and are frequently fluted like columns. The Romans would seem to have preferred semi-detached columns, but for their amphitheatres and later times pilasters are employed, as in the upper story of the Colosseum. In the revival of Classic architecture, and especially in Italy, architects seem to have considered that no building was complete without a network of pilasters on every storey, and France and England followed their example; and not only externally but inside the great cathedrals and churches the pilaster is adopted as the simplest and best way of dividing the bays.

PILATE, POINUS, the Roman governor of Judea under whom Jesus Christ suffered crucifixion. Of equestrian rank, his name Pontius suggests a Samnite origin, and his cognomen in the gospels, pilatus (if derived from the pilus or cap of liberty), descant from a freedman. In any case he came in A.D. 26 from the household of Tiberius, through the influence of Sejanus, to be procurator over part of the imperial province of Syria, viz. Judea, Samaria and Idumea. He ruled ten years, quarreled almost continuously with the Jews—whom Sejanus, diverging from the Caesar tradition, is said to have disliked—and in A.D. 36 was recalled. Before he arrived Tiberius died, and Pilate disappears from history. Eusebius relates (Hist. eccl. ii. 7)—but three centuries later and on the authority of earlier writers unnamed—that he was exiled to Gaul and committed suicide at Vienne.

Pilate kept the Roman peace in Palestine but with little understanding of the people. Sometimes he had to yield; as when he had sent the standards, by night, into the Holy City, and was besought for five days by suppliants who had rushed to Caesarea (Jos. Ant. 31; B. J. ii. ix. 3) not to hang up inscribed shields in Jerusalem, and was ordered by Tiberius to remove them to the other city (Philio ad Gaium 38). Sometimes he struck more promptly; as when the mob protested against his using the temple treasure to build an aqueduct for Jerusalem, and he disguised his soldiers to disperse them with clubs (Jos. Ant. xviii. 3, 2); or when he "mingled the blood" of some unknown Galileans "with their sacrifices" (Luke xii. 3); or slew the Samaritans who came to Mt Gerizim to dig up sacred vessels hidden by Moses there (Jos. Ant. xviii. 4, 7)—an incident which led to his recall. Philo, whose "History of the Egyptians" was published in 41 A.D., says that Pilate was present at the crucifixion, "the holy name of Jesus having been written on a cross which he himself had set up at the place where the body was to be crucified". From what he heard, Pilate was convinced that the crucifixion was not an imitation of the Romans, who had not "delivered Him to be crucified".

A more discriminating light is thrown upon him by the New Testament narratives of the trial of Jesus. They illustrate the right of review or recognitio which the Romans retained, at least in capital causes; the charge brought in this case of acting adversus majestatem populi romani; the claim made by Jesus to be a king; and the result that his judge became convinced that the claimant was opposed neither to the public peace nor to the civil supremacy of Rome. The result is explained only by the dialogue, recorded exclusively in John, which shows the accused and the Roman meeting on the highest levels of the thought and conscience of the time. "I am come to bear witness unto the truth...Pilate answered, What is truth?" Estimates of Pilate's attitude at this point have varied infinitely, from Tertullian's, that he was "already in conviction a Christian"— jam pro sua conscientia Christianus— to Bacon's "jesting Pilate," who would not stay for a reply. We know only that to his persistent attempts thereafter to get his proposed verdict accepted by the people, came their fatal answer, "Thou art not Caesar's friend," and that at last he unwillingly ascended the bema (in this case a portable judgment-seat, brought for the day outside the Praetorium), and in such words, "This is ad cruceum "delivered Him to be crucified." Pilate's place in the Christian tragedy, and perhaps also in the Creed, stimulated legend about him in two directions, equally unhistorical. The Gospel of Nicodemus, written by a Christian (possibly as early as, Tischendorf thought, as the middle of the 2nd century), repeats the trial in a dull and diluted way; but adds not only alleged evidence of the Resurrection, but the splendid vision of the descensus ad inferos—the whole professing to be recorded in the Acta Pilati or official records of the governor. The Epistola Pilati gives Pilate's supposed account to Tiberius of the Resurrection; and the Paradisus Pilati relates how Tiberius condemned him and his wife Proca or Proculla, both Christian converts. All this culminates in Pilate being canonized in the Abyssinian Church (June 29), and his wife in the Greek (Oct. 27). On the other hand the Mars Pilati tells how when condemned by the emperor he committed suicide; and his body, thrown first into the Tiber and then the Rhone, disturbed both waters, and was driven north into "Losania," where it was plunged in the gulf near Lucerne and below Mt Pilatus (originally no doubt Pilatus or cloud-capped), from whence it is raised every Good Friday to sit and wash unveiling hands.

BIBLIOGRAPHY.—For legends see Tischendorf's Evangelia apocrypha (1863) and Apocryphal Gospels, Ante-Nicene Lib. (1880).

(A. T. I.)

PILATUS, LEO, or LEONTIUS [LEONIO PILATO] (d. 1360), one of the earliest promoters of Greek studies in western Europe, was a native of Thessalonica. According to Petarct, he was a Calabrian, who posed as a Greek in Italy and an Italian abroad. In 1360 he went to Florence at the invitation of Boccaccio, by whose influence he was appointed to a lecturership in Greek at the Studio, the first appointment of the kind in the west. After three years he accompanied Boccaccio to Venice on a visit to Petarct, whom he had already met at Padua. Petarct, disguised with his manners and habits, despatched him to Constantinople to purchase MSS. of classical authors.

Pilateus soon tired of his mission and, although Petarct refused to accompany him back again, sent sail for Venice. Just outside the Adriatic Gulf he struck a storm and lightning. His chief importance lies in his connexion with Petarct and Boccaccio. He made a bold and almost word for word translation of Homer into Latin prose for Boccaccio, subsequently sent to Petarct, who owed his introduction to the poet to Pilatus and was anxious to obtain a complete translation. Pilatus also furnished Boccaccio with the material for his genealogy of the gods, in which he made an ostentatious display of Greek learning.

See Gibbon, Decline and Fall, ch. 66; G. Voigt, Die Wiederbelebung des klassischen Alterthums (1893); H. Hody, De Graecis illustribus (1773); Teoría d'ella literatura italiana, v. 691.

PILAU, a favourite Eastern dish, consisting essentially of rice, boiled with nutmeg or other mace, fish or mutton, and flavoured with spices, safras, &c. The word appears in Persian, Turkish and Urdu, and has been adopted in European languages. The term pilaff, showing the Turkish pronunciation, is also common.

PILCHARD (in earlier 16th century forms psycher, pilcher; of unknown origin; the Fr. pilisir is adapted from Eng.), Clupea pilchardus, a fish of the herring family (Clupeidaceae), abundant in the Mediterranean and on the Atlantic coasts of Europe, north to the English Channel. Sardine is another name for the same fish, which on the coast of Britain and Normandy is also called citan or cétren. It is readily distinguished from the other European species of Clupea. The operculum is sculptured with ridges radiating and descending towards the suboperculum; the scales are large, about thirty along the lateral line, deciduous; the ventral fins are inserted below, or nearly below, the middle of the base of the dorsal fin; the dorsal fin has seventeen or eighteen, the anal from nineteen to twenty-one rays. A small blackish spot in the scapular region is very constant, and sometimes succeeded by other similar marks. There are no teeth on the palate; pyloric appendages exist in great numbers; the vertebrae number fifty-three. The pilchard is one of the most important fishes of the English Channel. It spawns at a distance from the shore, and its eggs are buoyant, like those of many other marine fishes and unlike those of the herring, which are adhesive and demersal, i.e. develop under water. The egg of the pilchard is very easily disengaged from other pelagic eggs by the unusually large space separating the vitelline membrane from the contained ovum. Spawning takes place in summer, the season extending from June to October. When commencing their migrations towards the land the schools consist of countless numbers, but they break up into smaller companies near the shore. Pilchards feed on minute crustaceans and other pelagic animals and require two or three years before they attain their full size, which is about 10 in. in length. The sardines of the west coast of France, which are tinned in oil for export, are immature fish of the same stock as those taken on the coasts of Cornwall; they are 5 to 7½ in. in length, and though such fish occur also on the Cornish coast it is only in small numbers and for brief periods. In the Mediterranean the sardine does not exceed 7½ in. in length when mature. On the Pacific coast of America, in New Zealand and in Japan a pilchard occurs (Clupea sageri) which in its characters and habits is so similar to the European pilchard that its general utilization is deserving of attention. Immense shoals are reported to visit the east coast of Otago every year in February and March. Clupea scombrina is the "oil sardine" of the east coast of India.

(P. C. J.)

PILE, an homonymous word, of which the main branches are (1) a heap, through Fr. from pila, pillar; (2) a heavy beam used in making foundations, literally a pointed stake, an adaptation of Lat. pileum, jaceum; (3) the nautical pile, Lat. pilus, hair. In the first branch the Lat. pilis (for pilae, from Pers. panger, to fasten) meant also a pillar or mole of stone, hence any mass of masonry, as in Fr. pile. In English usage the word chiefly means a "heap" or "mass" of objects laid one on the top of the other, such as the heap of faggots or other combustible material on which a dead body is cremated, "funeral pile," or on which a living person is burnt as a punishment. It also is applied to a large and lofty building, and specifically, to a stand of arms, piled "in military fashion, and to the series of plates, "galvanic" or "voltaic piles," in an electric battery. The Middle English head and tail of a coin was formerly called "pilchard" or "pile," Fr. croix et pile, in modern Fr. face et pile. In the older apparatus for minting the die for the reverse was placed on a small upright pillar, pile, the other on a punchen known as a "trussel" (Fr. trousseau). The common name of the disease of haemorrhoids (q.v.) or "piles" is probably an extension of this word, in the sense of mass, swelling, but may be referred to the Lat. pilis, ball. The name of the pilum, or heavy javelin (lit. pounder, pestle, from pinnere, pisse, to beat), the chief weapon of the ancient Roman infantry, was adopted into many Teutonic languages in the sense of dart or arrow, cf. Germ. Pfeil; in English it is chiefly used of a heavy stake with one end sharpened, and driven into swampy ground or in the bed of a river to form the first foundations for a building; the primitive lake-dwellings built on "piles" are also known as "pile-dwellings." For the use of piles in building see FOUNDATIONS and BRIDGES. In heraldry a charge represented by two lines meeting in the form of an arrow head is known as a "pil," a direct adaptation probably of the Lat. pilum. The division of this intricate word, followed here, is that adopted by the New English Dictionary; other etymologyists (e.g. Skeat, Etym. Dict., 1898) arrange the words and their Latin originals somewhat differently.

PILGRIM, a wanderer, traveller, particularly to a holy place (see PILGRIMAGE). The earliest English forms are pilgrum or plegerum, through Fr. pilier (the original O. Fr. plegere is not found), from Lat. peregirus, a stranger, foreigner, particularly a resident alien in Rome (see PRATORI, and ROMAN LAW). The Lat. pereger, from which peregirus is formed, meant "from abroad," "travelled through many lands" (per, through, and ager, country).

It was customary for pilgrims to bring back as proof of their pilgrimage to a particular shrine or holy place a badge, usually made of lead or pewter, bearing some figure or device identifying it with the name or place. These "pilgrim signs" are frequently alluded to in literature—notably in the Canterbury Tales and in Piets Plowman. The British Museum and the Musée Cluny in Paris have fine collections of them, mainly dredged from the Thames and the Seine. The badges were generally worn fastened to the pilgrim's hat or cape. Among the best known are those of the cockle or scallop shell of St. James of Compostella in Spain; the "vernicile," a representation of the miraculous head of Christ; the vera icon, true image, on St. Veronica's handkerchief, at Rome, or of the Agbar portrait at Genoa, of "a vernicile hadde he sowed on his cappe" (Cant. Tales, "Prolo." 683); the Amiens badge of the head of John the Baptist on the charger, the cathedral claiming the custody of the relic from 1206 (fig. 1); and the palm branches or cross of palm leaf, the
PILGRIMAGE

PILGRIMAGE is unknown. (From Pilgrim's picturesque 1220. Hierapolis has The 1608 Some- houses to houses Wrotham, Scale, Alton, (near Guildford, and in martyrdom hollies still sometimes sometimes the ancient yews, hollyes or oaks which once bordered it. To this old track the name of 'pilgrim's way' has been given, for along it passed the stream of pilgrims coming through Winchester from the south and west of England and from the continent of Europe by way of Southampton to Canterbury Cathedral to view the place of the martyrdom of Thomas Becket, in the north transept, to the relics in the crypt where he was first buried after his murder, in 1170, and the shrine in the Trinity Chapel which rose above his tomb after the translation of the body in 1220. There were two festivals for the pilgrimage, on the 29th of December, the day of the martyrdom, and on the 7th of July, the day of the translation. The summer pilgrimage naturally became the most popular. In 1538 the shrine was destroyed and the relics of the saint scattered, but the great days of the pilgrimage had then passed. Erasmus gives a vivid picture of the glories of the shrine and of all that was shown to the pilgrims on his visit with Colet to Canterbury in 1534.

The principal villages, towns and places near or through which the way passed are as follow: Winchester, Alresford, Ropley, Alton, Farnham (here the way follows the present main road), Seale, Puttenham, by the ruined chapel of St Catherine, outside Guildford, near where the road crosses the Wey above Shalford, and by the chapel of St Martha, property of "the martyr," now restored and used as a church, Albury, Shere, Gomshall, Dorking (near here the Mole is crossed), along the southern slope of Boxhill to Reigate, then through Gatton Park, Merstham, Oxted, Wrotham, after which the Medway was crossed, Burham, past the megalithic monument Kit's Coty House, and the site of Boxley Abbey, the oldest after Waverley Abbey of Cistercian houses in England, and famous for its miraculous image of the infant saint Rumbold, and the still more famous winking rood or crucifix. The road passes next by Hollingbourne, Lenham and Charing. At Oxted, Wrotham and Charing were manor houses or rather palaces of the archbishops of Canterbury; at Hollingbourne was a manor of the priors of Christchurch. After

* Shalford Fair, the chapels on the two hills and the Surrey hills are probably the scene of Bunyan's Pilgrim's Progress, see E. Rémondard James, Notes on the Pilgrim's Way in West Surrey (1871).

Hollingbourne come Westwell, Eastwell, Boughton Aluph, Godmersham, Chilham Castle, and then at Harbledown, where are the remains of the Hospice of St Nicholas, the road joins Watling Street, by which came the main stream of pilgrims from London, the North and the Midlands.

This road, although its name of the Pilgrims' Way has for long confined it to the road by which the pilgrims came to Canterbury from Winchester, follows a far older track. Right back into British and even older times the main direction which commerce and travellers followed across southern and western England to the Straits of Dover and the Continent lay from Canterbury along the southern chalk slope of the North Downs to near Guildford, then by the Hog's Back to Farnham. At this point the oldest track went across Salisbury Plain towards Stonehenge and so on to Cornwall. From Farnham westward the only portion of this the oldest track that can now be traced is a small portion that still bears the name of the Harrow (i.e. hoary, old) road. It was in early times abandoned for the road from Winchester to which the stream of travel and commerce from the Continent and the south and west of England was diverted.

The English "Pilgrims' Way."—From Winchester, in Hampshire, to Canterbury, in Kent, runs a road or way which can still be traced, now on the present made roads, now as a lane, bridle path, or cart track, now only by a line of ancient yews, hollies or oaks which once bordered it. To this old track the name of "pilgrim's way" has been given, for along it passed the stream of pilgrims coming through Winchester from the south and west of England and from the continent of Europe by way of Southampton to Canterbury Cathedral to view the place of the martyrdom of Thomas Becket, in the north transept, to the relics in the crypt where he was first buried after his murder, in 1170, and the shrine in the Trinity Chapel which rose above his tomb after the translation of the body in 1220. There were two festivals for the pilgrimage, on the 29th of December, the day of the martyrdom, and on the 7th of July, the day of the translation. The summer pilgrimage naturally became the most popular. In 1538 the shrine was destroyed and the relics of the saint scattered, but the great days of the pilgrimage had then passed. Erasmus gives a vivid picture of the glories of the shrine and of all that was shown to the pilgrims on his visit with Colet to Canterbury in 1534.

gave rise to all manner of religious expeditions. Even among the Israelites, the visitation of certain cult-centres prevailed from remote antiquity; but, when the restriction of Yahweh-worship to Jerusalem had doomed the old shrines, the Jewish pilgrimages were directed solely to the sanctuary on Mt Moriah.

Among the Greeks the habit was no less deeply rooted. Just as the inhabitants of each town honoured their tutelar deity by solemn processions to his temple, so, at the period of the Olympic games, the temple of Zeus at Olympia formed the goal of multitudes from every Hellenic country. No less powerful was the attraction exercised by the shrines of the oracular divinities, though the influx of pilgrims was not limited to certain days, but, year in and year out, a stream of private persons, or embassies from the city-states, came flowing to the temple of Zeus in Dodona or the shrine of Apollo at Delphi.

The unification of the peoples of antiquity in the Roman Empire, and the resultant amalgam of religions, gave a powerful impetus to the custom. For, as East and West still met at the old sanctuaries of Greece, so—and yet more—Greece and Rome repaired to the temples of the southern and eastern deities. In the shrine of Isis at Philae, Europeans set up votive inscriptions on behalf of their Christian friends away at home, and it may be surmised that even among the festival crowds at Jerusalem a few Greeks found place (John xii. 20).

The pilgrimage, however, attained its zenith under Islam. For Mahomet proclaimed it the duty of every Mussulman, once at least in his life, to visit Mecca; the result being that the birthplace of the Prophet is now the religious centre of the whole Mahommedan world (see Mahommedan Religion; Caravan; Mecca).

II. The Pilgrimage under Christianity.—The pilgrimages of Christianity presuppose the existence of those of paganism; but it would be an error to maintain that the former were a direct development of the latter. For primitive Christianity was devoid of any point by which these journeys of devotion might naturally have been suggested. It was a religion without temples, without sanctuaries, and without ceremonial. The saying of the Johannine Gospel—that God is to be adored neither in Jerusalem nor on Gerizim, but that His true worshipper must worship Him in spirit and in truth—is in complete harmony with the old Christian piety. And, accordingly, in the ancient Christian literature, we find no trace of a conception that the believer should visit a definite place in order to pay homage to his Master. The evolution of the Christian pilgrimage moved on other lines.

If finely observes that, in Athens, the glorious architecture caused him less pleasure than did the thought of the great men whose work was done in its midst—"how here one had lived, and there fallen asleep; how here another had disputed, and there lay buried" (De Legg. ii. 2). This feeling was not weakened by the advent of Christianity, in fact, we may say that it was appreciably strengthened. Cicero had already compared the sites consecrated by the memory of some illustrious name with those hallowed by recollections of a loved one. But with the Christian, when his Redeemer was in question, both motives coincided: for there the greatest was also the dearest.

In this devotion to the memory of Jesus and to the key to the origin of the Christian pilgrimage: the faithful repaired to those places which were invested with memories of their Lord's earthly life. And these journeys must certainly date from the 2nd century. For Origen (d. 254) mentions that in Bethlehem the cave was shown where Christ was born, and in it the manger in which Mary made the bed of her child. The site must have been much visited long before this, since Origen remarks that it was common knowledge, even among the infidels, that there was the birthplace of that Jesus whom the Christians worshipped (Contr. Cels. i. 51). But those who visited Bethlehem must certainly have visited Jerusalem and the places there, so rich in memorials of their Master. And the sympathy of Christendom soon let them beyond this immediate circle. The anonymous author of the Cohortatio ad Graecos, a work of the 2nd century, visited the remnants of those cells, in which—so legend related—the seventy interpreters laboured on their version of the Old Testament: nor, when he came to Cumae in Campania, did he fail to have shown him the old shrine of the Sibyl (Coh. ad Gr. 13 and 37). Soon we begin to hear the names of the pilgrims. In the course of the 3rd century, as Jerome relates, Firmilian, bishop of Caesarea in Cappadocia, travelled to Palestine to view the sacred places (De Vir. ill. 54); while, according to Eusebius, a second bishop from Cappadocia, Alexander by name, visited Jerusalem in order to pray and acquaint himself with the holy sites, and was there invited by the community to remain with them and assume the episcopate of the aged Narcissus (Hist. eccl. vi. 11). With regard to his own time, the early years of the 4th century—the same authority recounts that believers kept streaming to Palestine from all regions, there to offer their prayers at a cavern shown on the Mount of Olives (Demonstr. evang. vi. 18).

This statement, that the Christians of the 3rd and 4th centuries were in the habit of visiting Jerusalem for prayer, proves that the non-Christian conception of the religious pilgrimage had already entered the sphere of Christian thought. That men travelled for purposes of prayer implies acceptance of the heathen theory of sanctuaries which it is an act of piety to visit. We find the same theory in the Christian Calendar, which regarded the shrines as especially holy to Christian thought. Nevertheless, it is clear that the development was inseparable. As soon as the non-Christian ideas of priests, sacrifices, houses of the god, and so forth, were naturalized in the Christianity of the 3rd century, it was but a short step to the belief in holy places.

III. The Pilgrimage in the Ancient Church.—In the passages cited above, Bethlehem and the Mount of Olives figure as the main goal of the pilgrimage: and on the Mount of Olives the mind must naturally turn to the Garden of Gethsemane and the scene of the Ascension. It may seem surprising that there is no mention of Golgotha and the Sepulchre. But the visitation of these sites was rendered impossible to the Christians by the destruction of Jerusalem and the erection of the town of Aelia Capitolina. They had not forgotten them; but the grave was concealed under a mound of earth and stones—a profanation probably dating from the siege of the city and Titus's attack on the second wall. On the summit of this mound there stood, in the days of Eusebius, a sanctuary of Venus (Eus. Vit. Const. ii. 26, 30). The Sepulchre and the Hill of the Crucifixion were lost to the Christian pilgrim; and, consequently, before the era of Constantine, the one holy site in the town of Jerusalem was the so-called Conseculum, which received its name in later years. It lay south of the city, near the outer wall, and, if Epiphanius is to be believed, was already in existence when Hadrian (130-131) visited Jerusalem (De mens. 14). It was regarded as the house, in which —according to the Acts of the Apostles (xii. 12 sqq.)—Mary, the mother of John Mark, lived; and the belief was that there the Lord kept the Last Supper, and that there the eleven assembled after the Ascension. It was there, also, that the scene of the Pentecostal effusion of the Spirit was laid (cf. Cyrill. Hier. Cat. xvi. 4).

The pilgrimage to Palestine received a powerful impetus from the erection of the memorial churches on the holy sites, as described by Eusebius in his biography of the emperor (iii. 25 sqq.). At the order of Constantine, the shrine of Venus above mentioned was destroyed, and the accumulated rubbish removed, till the ancient rock-foundation was reached. There the cave was discovered in which Joseph of Arimathea had laid the body of Jesus; and above this cave and the Hill of the Crucifixion the imposing church of the Holy Sepulchre was built (A.D. 326-336). The churches in Bethlehem and on the Mount of Olives were erected by Helena, the mother of Constantine, who herself undertook the pilgrimage to the Holy Land. These churches were then endowed with new sanctuaries of miraculous powers, and relics of Christ were copied in their shape of the Cross and the nails. Eusebius, the contemporary of Constantine, is silent on this point. To his continuators, on the other hand, it is an established fact that Helena brought all three crosses to light, and ascertained
the genuine Cross by the instrumentality of a miracle, in addition to discovering the nails of the Crucifixion (Ruini. i. 7; Socr. i. 17; Sozomen. ii. 11; Theod. i. 17). It is impossible to fix the date at which the supposititious relics were introduced into the church of the Sepulchre: it is certain, however, that in the 5th century the Cross was there preserved with scrupulous reverence, and accounted the highest treasure of the sanctuary.

After the 4th century, monks and nuns begin to form no inconsiderable part of the pilgrimages—a fact which is especially manifest from the numerous notices to be found in Jerome, and the narratives of Theodoret in the Histories. In fact, many were inclined to regard a journey to Jerusalem as the bounden duty of every monk—an exaggerated view which led to energetic protests, especially from Gregory of Nyssa, who composed a monograph on the pilgrimages (De iis qui adeunt Hierosol.). Jerome, like Gregory, insists on the point that residence in Jerusalem has in itself no religious value: it is not locality, but character, that avails, and the gates of Heaven are as open in Britain as in Jerusalem (Ep. 58, 3). These utterances, however, must not be misinterpreted. They are not directed against the pilgrimage in itself, nor even against the belief that prayer possesses special efficacy, so much as against the exaggerated developments of the system.

The theologians of the 4th and 5th centuries were at one in recognizing the religious uses of the pilgrimages. Jerome in particular considered it an act of faith for a man to offer his prayers where the feet of the Lord had stood, and the traces of the Birth, of the Cross, and of the Passion were still to be seen (Ep. 47, 2).

We may gain some impression of the mood in which the pilgrims completed their journey, when we read how Paul, the friend of Jerome, expresses herself on her visit to the church of the Sepulchre: "As oft as we enter its precincts we see the Saviour laid in the shroud, and the angel seated at the feet of the dead!" (Hieron. Ep. 46, 2). She assured Jerome that, in the church of the Nativity at Bethlehem, she beheld, with the eye of faith, the Child-Christ wrapped in swaddling clothes (Ep. 108, 10). But with these thoughts, others of an entirely different stamp were frequently blended. Pilgrimages were conceived as means to ensure an answer to particular prayers. So, for example, Eudocia, the wife of Theodosius II., vowed to undertake a pilgrimage to Jerusalem, if she should see her daughter married. (Socr. Hist. ecc. vii. 47). And, closely as this approaches to parallelism in the distinction between paganism and Christianity is completely obliterated when we find the hermit Julian and his companions travelling to Sinai in order to worship the Deity there resident (Theod. Hist. Rel. 2).

With the number of the pilgrims the number of pilgrim-resorts also increased. Of Jerusalem alone Jerome relates that the places of prayer were so numerous that it was impossible to visit them all in one day (Ep. 46, 9). In the Holy Land the list was still longer: the natives were ready to show everything for which the foreigner inquired, and the pilgrim was eager to credit everything. In her expedition to the East, the Paula mentioned above visited, among other places, the church of Caesarea. In the first-named place she was shown the tower of Elijin; in the second, the house of Cornelius, that of Philip, and finally the grave of the four virgins. At Bethlehem she saw, in addition to the church of the Nativity, the grave of Rachel; at Hebron the hut of Sarah, in which the swaddling clothes of Isaac and the remains of Abraham’s oak were on view (Hier. Ep. 108). A similar picture is given in the Travels of the so-called Silvia Aquitana, who seems, in reality, to have been a Spanish nun, named Etheria or Eucheria. She went as a pilgrim to Jerusalem (c. 380), and from there traversed the length of Palestine, in order to visit every site which was consecrated by memories of the Lord’s earthly life. Nor did she neglect the scenes of patriarchal history. Of greater antiquity is the concise account of his travels by an anonymous pilgrim, who, in A.D. 333, undertook the journey from Bordeaux to Palestine. The Itinerary of the African Theodosius who visited the East between A.D. 520 and A.D. 530 is of later date (P. Geyer, Itin. Hierosol. sac. iv–viii.).

While pilgrim-resorts were thus filling the East, their counterparts began to emerge in the West. And here the starting-point is to be found in the veneration of martyrs. In the West, Care for the tombs of martyrs was sanctioned by immemorial custom of the Church; but, in this case also, a later age failed to preserve the primitive conception in purity; and Augustine himself was obliged to defend the usage of the Church from the imputation that it implied a transference of heathen ceremonial to the sphere of Christianity (Contr. Faust. xx. 21). The martyrs were the local heroes of particular communities; but there were men whose life and death were of significance for the whole of Christendom—the apostles. Of these Peter and Paul had suffered martyrdom in Rome, and it was inevitable, from the nature of the case, that their graves should soon become a resort, not only of Romans born, but of strangers also. True, the presbyter Caius (c. 200) who first mentions the situation of the apostolic tombs on the Vatican and other places refers to Origen as having said nothing to support this Christian veneration of the same in order to visit them. And though Origen travelled to Rome, it was not to view the graves of dead men, but to establish relations with the living flock (Euseb. Hist. ecc. ii. 25, 7; vi. 14, 10); still, it is certain that the Roman cemeteries were visited by numerous pilgrims even in the 3rd century: for the earliest graffiti in the papal crypt of the Coemeterium Callistianum must date from this period (De Rossi, Roma sotterr. i. 253 sqq.; Kraus, ROM. Sot. 148 sqq.). And if the tombs of the popes were thus visited, so much more must this hold of the tombs of the apostles. After these, the most frequented resort at Rome in the 4th century was the grave of Hippolytus. The poet Prudentius describes how, on the day of the martyr’s death, an innumerable multitude of pilgrims flocked round the site. Even on ordinary days arrivals and departures were almost incessant—foreigners being everywhere seen mingled with the native Latins. They poured balsam on the sepulchre of the saint, washed it with their tears, and covered it with their kisses, in the belief that they were thus assuring themselves of his intercession or testifying their gratitude for his assistance. Prudentius says of himself, that whenever he was sick in soul or body, and prayed there, he found help and returned in cheerfulness: for God had vouchsafed His saint the power to answer prayers (Ep. 140, 175 sqq.). Paulinus of Nola (d. 431) concurs—his custom being to visit the sepulchre, and Rome on the apostolic anniversaries (Ep. 20, 2; 45, 1). Next to Rome the most popular religious resort was the tomb of Felix of Nola (August. Ep. 78, 3); while in Gaul the grave of St Martin at Tours drew pilgrims from all quarters (Paul. Nol. Ep. 17, 4). Africa possessed no sanctuary to compete with these; but we learn from Sulpicius Severus (c. 400) that the tomb of Cyprian seems to have been visited even by a Gaul (Dial. 1, 3).

The motive that drew the pilgrims to the graves of the saints is to be found in the conviction, expressed by Prudentius, that the divine succour was certain; and hence came the belief in a never-ending series of miracles there performed (c.f. e.g. Ennod. Ticin. Lib. pro syn. p. 315). Doubt was unknown. St Augustine observes that, though Africa was full of martyrs’ tombs, no miracle had been wrought at them so far as his knowledge extended. This, however, did not lead him to doubt the truth of those reported by others—a fact that is somewhat surprising when we reflect that the phenomenon caused him much disquiet and perplexity. Who, he asks, can fathom the design of God in ordaining that this should happen at one place and not at another? And eventually he acquiesces in the conclusion that God, who gives every man his individual gift at pleasure, has not willed that the same powers should have efficacy at every sepulchre of the saints (Ep. 78, 3).

IV. The Pilgrimage in the Middle Ages.—The medieval Church
adopted the custom of the pilgrimage from the ancient Church. The young Germanic and Romance nations did precisely as the Greek and Romans had done before them, and the motives of these devotional journeys—now much more difficult of execution in the general decay of the great world-system of commerce—remained much the same. They were undertaken to the honour of God (Pipp. Cap. 754-755, c. 4), for purposes of prayer (Ann. Hild. 992), or in quest of assistance, especially health (Vita Galli, ii. 37; Vita Liudg. iii. 10). But the old causes were reinforced by others of at least equal potency. The medieval Church was even more profoundly convinced by its predecessor that the miraculous power of Deity attached to the bodies of saints and martyrs. But the younger nations—French, English, and German—were scantily endowed with saints; while, on the other hand, the belief obtained that the home-countries of Christianity, especially Rome and Jerusalem, possessed an inexhaustible supply of these sanctified bodies. Pilgrimages were consequently undertaken with the intention of securing relics. At first it was enough to acquire some object which had enjoyed at least a mediate connexion with the hallowed corpse. Gregory of Tours (d. 594) mentions one of his deacons who made a pilgrimage into the East, in order to collect relics of the Oriental saints; and, on his return, visited the grave of the bishop of Seligenstadt (St. Nizier, d. 573) in Lyons, where he still further increased his store. His testimony showed how relics came to be distributed among the populace: one enthusiast took a little wax dropped from the taper; another, a portion of the dust which lay on the grave; a third, a thread from the cloth covering the sarcophagus; and he himself plucked the flowers which visitors had planted above the tomb. Such were the memorials with which he returned; but the universal belief was that something of the miraculous virtue of the saint had passed into these objects (Vis. patr. 8, 6). Before long, however, these humble trophies failed to content the pilgrims, and they began to devote their efforts to acquiring the actual bodies, or portions of them—frequently by honest means, still oftener by trickery. One of the most attractive works of early mediævalism—Einhard's little book, Translatio Marcellini et Petri—gives a vivid description of the methods by which the bodies of the two saints were acquired and transported from Rome to Seligenstadt on the Main.

Far more important consequences, however, resulted from the fact that the medieval mind associated the pilgrimage with the forgiveness of sins. This conception of the pilgrimage, as a means of expiation or a source of pardon for wrong, was foreign to the ancient Church. It is quite in accordance with the keener consciousness of sin, which pervades in the Middle Ages, that the expiatory pilgrimage took its place side by side with the pilgrimage to the glory of God. The pilgrimage became an act of oblation; and, in the books of penance (Poenitentialia) which date from the early middle ages, it is enjoined—whether for a definite period (e.g. Poen. Valicell. i. c. 19; Theod. Cant. i. 2, 16) or for life (Poen. Cummeani, vii. 12, Casin. 24)—as an expiation for many of the more serious sins, especially murder or the less venial forms of unchastity. The place to be visited was not specified; but, the pilgrim, who was bound by an open letter of his bishop to discharge himself as a penitent, lay under the obligation, wherever he went, to repair to the churches and—more especially—the tombs of the saints, and there offer his prayers. On occasion, a chain or ring was fastened about his body, that his condition might be obvious to all; and soon all manner of fables gained currency: how, here or there, the iron had sprung apart by a miracle, in token that the sinner was thereby absolved by God. For instance, the Vita Liudgeri recounts the history of a fraticide who was condemned to this form of pilgrimage by Jonas, bishop of Orleans (d. 843); he wore three iron rings round his body and arms, and travelled bare-footed, fasting, and devoid of linen, from church to church till he found pardon, the first ring breaking by the tomb of St Gertrude at Nivelles, the second in the crypt of St Peter, and the third by the grave of Liudger. The pilgrim-age with a predetermined goal was not recognized by the books of penance; but, in 1059, Peter Dainiani imposed a pilgrimage to Rome or Tours on the clerics of Milan, whom he had absolved (Acta mediiiv. patroil. lat. 145, p. 98).

As the system of indulgences developed, a new motive came to the fore which rapidly overshadowed all others: pilgrimages were now undertaken to some sacred spot, simply in order to obtain the indulgence which was vested in the respective church or chapel. In the 11th century the indulgence consisted in a remission of part of the penance imposed in the confessional, in return for the discharge of some obligation voluntarily assumed by the penitent. Among these obligations, a visit to a particular church, or the bestowal of pious gifts upon it, held a prominent place. The earliest instance of the indulgential privilege conferred on a church is that granted in 1216 by Pontius, archbishop of Arles, to the Benedictine abbey of Montmajour (Mons Major) in Provence (d'Achery, Spicil. iii. 383 seq.). But these dispensations, which at first lay chiefly in the gift of the bishops, then almost exclusively in that of the popes, soon increased in an incessant stream, till at the close of the middle ages there were thousands of churches in every western country, by visiting which it was possible to obtain an almost indefinite number of indulgences. But, at the same time, the character of the indulgences changed. From the 11th century the remission of penance it was extended, in the 13th century, to a release from the temporal punishment exacted by God, whether in this life or in purgatory, from the repentant sinner. And, from an absolution from the consequences of guilt, it became, in the 14th and 15th centuries, a negation or the guilt itself; while simultaneously the opportunity was offered of acquiring an indulgence for the souls of those already in purgatory. Consequently, during the whole period of medievalism, the number of pilgrims was perpetually on the increase.

So long as the number of pilgrims remained comparatively small, and the difficulties in their path proportionately great, only the more important churches could obtain indulgences or receive from their bishops to the clergy and laity, which ensured them lodging in convents and charitable foundations, in addition to the protection of public officials. An instance is preserved in Markulf's formulayi. 49). To receive the pilgrim and supply him with alms was always considered the duty of every Christian: Charlemagne, indeed, made it a legal obligation to withhold neither roof, hearth, nor fire from them (Admon. gent. 786, c. 75; Cap. Miss. 852, c. 27).

The most important places of resort both for voluntary and involuntary pilgrimages, were still Palestine and Rome. On the one hand, the old gloriametra, the abbot Adaman of Jona (d. 764) now composed his monograph De locis sanctis, which served as the basis of a similar book by the Venerable Bede (d. 735)—both works being edited in the Illust. hierosol. His authority was a Frankish bishop named Arculf, who resided for nine months as a pilgrim in Jerusalem, and visited the remaining holy sites of Palestine in addition to Alexandria and Constantinople. Of the later itineraries the Descriptio terrae sanctae, by the Dominican Burchardus de Monte Sion, enjoyed the widest vogue. This was written between the years 1285 and 1295; but books of travel in the modern tongues had already begun to make their appearance. The initiative was taken by the French in the 13th and 14th centuries, and the Germans followed in the 14th and 15th; while the Book of Wayes to Jerusalem of John de Maundevile (c. 1356) attained extreme popularity, and was translated into almost all the vernacular languages. Most pilgrims, probably, contented themselves with the brief guide-books which seem to have originated in the catalogues of indulgences. In later periods, that of Romberch a Kyrsepe, printed at Venice (1519), stood high in favour.

A long list might be compiled of men of distinction who performed the pilgrimage to Palestine. In the 8th century one of the most famous is the Anglo-Saxon Willibald, who died in 781 as bishop of the Frisian diocese of Bremen. He left his home in the spring of 770, accompanied by his father and brother. The pilgrims traversed France and Italy, visiting

PILGRIMAGE 607
PILGRIMAGE

every religious resort; in Lucca the father died, and the brother
remained behind in Rome. Early in 1522 Willibald began his
expedition to the Holy Land alone, except for the presence of
two companions. He travelled past Naples to Syracuse, then
on shipboard by Cos and Samos to Ephesus, and thence through
Asia Minor to Damascus and Jerusalem. On St Martin's
day, in 724, he arrived in the Holy City. After a prolonged
stay in the town and its environs, Willibald proceeded (727)
to Constantinople, and in 729 returned to Italy. Such is the
account given by the nun of Heidenheim in her biography of
Willibald; and her version is probably based on notes by the
pilgrim himself (Mon. Germ. hist. ser. xvi. 80 sqq.). In the
9th century the French monk Bernard visited Palestine with
two companions, and afterwards wrote a simple and trust-
worthy account of his journey (Patrol. lat. 121, 559 sqq.).
In the 10th century, Conrad, bishop of Constance (934-976),
performed the pilgrimage to Jerusalem three times (Vita Chonon. 7);
and to the same period belong the first women-pilgrims to
Jerusalem of whom we have any cognisance—Hidda, mother of
Gero, archbishop of Cologne (Thietm. Chron. ii. 16), and the
countess Hademod of Elbersberg (Chron. ebersb.'). The leaders,
moreover, of the monkish reform movement in the 11th and
12th centuries, Richard of St Victor, in fact, hardly even
began the Cravath movement (727-1045), had seen the Holy Land
with their own eyes (Vita Rich. 17; Vita Poppo. 3). In the
year 1028 Archbishop Poppo of Trier (d. 1047) undertook a
pilgrimage which led him past Jerusalem to the banks of the Euphrates,
his return taking place in 1030 (Gesta Trevir. Cont. i. 4 seq.).
But the most celebrated devotional expedition before the Crusades
was that of the four bishops—Sigrid of Mainz, Gunther of
Bamburg, William of Utrecht, and Otto of Regensburg.
They set out in 1064, with a company whose numbers exceeded
seven thousand. The major portion, however, fell in battle
against the Mahommedans, or succumbed to the privations of
the journey, and only some two thousand saw their homes
again (Annal. Alth., Lamb., Disib., Marian. Scot. kc.). Among
the followers of the bishops were two clerics of Bamberg, Ezzo
and Wille, who composed on the way the beautiful song on
the miracles of Christ—one of the oldest hymns in the German
language. The text was due to Ezzo, the tune to Wille (Müllen-
bof and Scherer, Denkmäler, i. p. 78, No. 31). A few years later
Count Dietrich of Trier began a pilgrimage to Jerusalem with
113 companions, in atonement for the murder of Archbishop
Kuno. The ship, however, which conveyed them down with
all hands in a storm (Berth. Ann. 1173).

As a result of this steady increase in the number of pilgrims,
the old arrange for the accommodation of the pilgrims
were found deficient. Consequently hospices arose which were designed
exclusively for the pilgrim. Those on the Alpine passes are
common knowledge. The oldest, that on the Septimer pass,
dates from the Carolingian period, though it was restored in
1120 by the bishop Wido of Chur: that on the Great St Bernard
was founded in the 10th century, and reorganized in the 13th.
To this century may also be assigned the hospice on the Simpion;
to the 14th those on the St Gothard and the Lukaner. Similarly,
the Mediterranean towns, and Jerusalem in particular,
bad their pilgrim-refuges. Service in the hospices was regularly
performed by the hospital-hospitals—that is to say, by lay
associations working under the authorization of the Church.
The most important of these was the fraternity of the Hospital
eirosomylanum, founded between 1065 and 1075; for hence
arose the order of St John, the earliest of the orders of
knighthood. In addition to the hospital of Jerusalem, numerous
others were under its charge in Acre, Cyprus, Rhodes, Malta,
&c. Associations were formed to assist pilgrims bound for the
East; one being the Confrérie des pèlerins de Terre-Sainte
in Paris, founded in 1325 by Louis de Bourbon, count of Clermont
(inafterwards first duke of Bourbon). Its church was in the rue
des Cordeliers. Similar institutions also existed in Amsterdam,
Utrecht, Antwerp, and elsewhere in the Netherlands.

But since, in the middle ages, the Holy Land was no longer
held by a Christian Power, the number of the pilgrims was
no less necessary than their sustenance. This fact, after the
close of the 11th century, led to the Crusades (q.v.), which in
many respects are to be regarded as armed pilgrimages.
For the old dream of the pilgrim, to view the country where God had
walked as man, lived on in the Crusades—a fact which is dem-
strated by the letters of Bernard of Clairvaux, with the songs
of Walther von der Vogelweide and other Crusaders. And, since
the strongest motive in the pilgrimage was the acquisition of
indulgences, unnumbered thousands were moved to assume
the Cross, when, in 1193, Urban II. promised them plenary
indulgences, on condition that they entered the commerce with Palestine,
and the erection of a Christian empire in Palestine, naturally
welcomed the influx of pilgrims. And though in 1187 the Holy
City again fell into the hands of the infidel, while in 1291
the loss of Acre eliminated the last Christian possession in Palestine,
the pilgrimages still proceeded. True, after the fall of the city
and the loss of Acre, they were forbidden by the Church; but
the veto was impracticable. In the 12th century these religious
expeditions were still so common that, every Sunday, prayers
were offered in church for the pilgrims (Honor. Aug. Spec. ecc.
p. 828). In the 13th century the annual number of those who
visited Palestine amounted to many thousands: in the 14th and
15th centuries the fact, between the years 1560 and 1563,
no fewer than 1400 men of distinction can be enumerated
from Germany alone who travelled to the Holy Land
(Röhrich and Meissner, Deutsche Pilgerreisen, pp. 445-456).
It was not till the Reformation, the wars of the 16th century,
and the loss of Rhodes, Candia and Cyprus to the Turks, that
any appreciable alteration was effected. When Ignatius de
Loyola (q.v.) set sail in 1523 from Venice to Palestine, only
some thirteen souls could be mustered on the pilgrimage-ship, while
eight or nine others sailed with the Venetian state- vessel as far as
Cyprus. A considerable number had abandoned their pilgrim-
age and returned home on the news of the fall of Rhodes (Dec.
22, 1522; see Acta sanct. Jul. viii. 642 seq.).

For pilgrimage overseas, as it was styled, the permission of the
Church was still requisite. The pilgrims made their journey
in grey cloths fastened by a broad belt. On the cowl they wore
a red cross; and a broad-brimmed hat, a staff, sack and gourd
completed their equipment. During their travels the beard
was allowed to grow, and they prepared for departure by confession
and communion. Of their hymns many are yet extant ("Jeru-
alem mirabilis," "In gottes namen faren wir," &c.). The embarcation
took place either in France or Italy. In France, Marseille was the main harbour for the pilgrims. From there
ships belonging to the Knights of St John and the knights
of the Templars conducted the commerce with Palestine, and carried
annually some 6000 passengers. In the Italian ports the number
of shipments was still greater—especially in Venice, whence the
regular passagium started twice a year. The Venetian pilgrim
ships, moreover, carried as many as 1500 souls. The pilgrims
formed themselves into unions, elected a "master" and
concluded their agreements, as to the outward voyage and return,
in common. After Venice, Genoa and Pisa occupied the most
prominent position. The voyage lasted from six to eight weeks,
the stay in Jerusalem averaging ten days. The visitation of the
holy places was conducted in processions headed by the Fran-
ciscans of the Convent of Zion.

The expenses of a pilgrimage to Palestine were no light matter.
In the 13th century they may be estimated at 100 marks of silver (£200) for the ordinary pilgrim. This was the amount
raised in 1147 by one Goswin von Randerath to defray the
Later the cost was put at 280-300 ducats (£140-£150). In the
13th century a knight with two squires, one groom, and the
 requisite horses, had to disburse 83 marks of silver for his passage,
while for a single pilgrim the rate was rather less than 1 mark.
In the 16th century Ignatius de Loyola calculated the cost of
the voyage from Venice to Jaffa at some 6 or 7 gold florins (£9).
The expenses of the princes and lords were, of course, much
heavier. Duke William of Saxony, who was in Jerusalem in
1401, spent no less than £10,000 on his journey (see Pruza.
PILGRIMAGE

Kulturgeschichte der Kreuzzüge, pp. 106 sqq.; Röhrich, Deutsche Pilgerreisen, p. 42.

Great was as the number of pilgrims overseas, it was yet far exceeded by that of the visitants to the "threshold of the apostles," i.e. Rome. As was the case with Jerusalem, guide-books to the city of the apostles were now composed. The oldest is the Notitia ecclesiarum urbis Romae, which was probably compiled under Honorius I. (625-638). The monograph De locis s. martyrum is of somewhat later date. Both are found in De Rossi, Roma sottoraneas, i. 138 sqq.). The Itinerarium einsidellense (ed. G. Hänel, Archiv. f. Philologie, v. 116) belongs to the second half of the 8th century. Its composer would seem to have been a disciple of Willigis. His interests are not confined to the churches, their reliquaries, and the ecclesiastical ceremonial of saint-days, but he takes a pleasure in transcribing ancient inscriptions. William of Malmsbury, again, when relating the crusade of Count Robert of Normandy (1096), transfers into his Gesta regum anglorum (iv. § 351) an old description of Rome, originally intended for the use of pilgrims.

The pilgrimages to Rome received their greatest impetus through the inauguration of the so-called Year of Jubilee (q.v.). On the 22nd of February 1350 the bull of Boniface VIII., Antiquarum habet fidem, promised plenary indulgence to every Roman who should visit the churches of the apostles Peter and Paul on thirty days during the year, and to every foreigner who should perform the same act on fifteen days. At the close of the Jubilee this dispensation was extended to all who had expired on the way to Rome. This placed the pilgrimage to Rome on a level with the crusades—the only mode of obtaining a plenary indulgence. The success of the papal bull was indescribable. It is computed that, in the Year of Jubilee, on an average, 200,000 strangers were present in the city during the day. The greatest number of the pilgrims came from southern France, England sending comparatively few on that occasion (see Gregorovius, Gesch. d. Sta. Rom. v. 546 sqq.). The Jubilee dispensation according to the edict of Boniface VIII. was to be repeated every century; but this period was greatly abridged by succeeding popes (see JUBILEE, YEAR OF), so that in the years 1350, 1359, 1473, 1459, 1475, 1500, the troops of pilgrims again came streaming into Rome to obtain the cherished dispensation.

Of the other pilgrimage restors, we shall only emphasize the most important. Priority of mention is due to St James of Compostella (Santiago, in the Spanish province of Galicia). Here the attraction for the pilgrim was the supposed possession of the body of James the son of Zebedee. The apostle was executed (A.D. 44) by command of Herod Agrippa (Acts xii. 1); and at the beginning of the medieval period it was believed that his corpse was laid in Palestine (Venant. Portion. Carol. v. 144, viii. 3). The first connexion of the apostle with Spain is to be traced in the Poema de aris b. Mar. et xii. apost. domic, which is ascribed to Aldegund (d. 709) and contains a story of his preaching in that country.

The earliest account of the transit of his relics to the Peninsula is found in Notker Balbulus (d. 912, Martyro. in Jul. xxvi). But in Spain belief in this cherished possession was universal; and, step by step, the theory won credence throughout the West. In 1599, Archbishop Wido of Milan journeyed to St James (Damiani, Acta mediol. p. 98); and a little later we hear of bands of pilgrims from Germany and France. In England, indeed, the shrine of St James of Compostella became practically the most favoured devotional resort; and in the 13th century its visitation had attained such popularity that a pilgrimage was granted on a level with one to Rome or Jerusalem (Honor. August. Spec. ecc. p. 829). In Paris, after 1410, there existed a special hospice for the "fraternity of St James," in which from 60 to 80 pilgrims were received each day, fed, and presented with a quarter of a denarius (Dulaure, Hist. de Paris (1842), i. 531). Even in the period of the Reformation the "Song of St James" was sung in Germany (Wackernagel, Kirchenlit., ii. No. 1246); and in 1478 pilgrimages to that shrine were placed by Sixtus IV. on official equality with those to Rome and Jerusalem (Extrav. comm. c. 5; De poenit. v. 9).

In France St Martin remained the chief goal of the pilgrim; while Notre Dame de Sous-Terre in Chartres (with a portrait of the "black Virgin"), Le Puy-en-Velay (dep. Haute Loire), and others, also enjoyed considerable celebrity. In England pilgrimages were made to the tomb of the murdered archbishop, Thomas Becket, in Canterbury Cathedral. The setting of Chaucer's Canterbury Tales gives a vivid idea of the motley company of pilgrims; but it seems probable that Germany also sent a contingent (Gervas. Contuar. cl. ann. i184; Ralph de Diceto, Ymag. hist. ann. i184). In addition, Walsingham, Peterborough, St Davids, Holywell, and St Andrews in Scotland were much frequented. In lower Germany, Cologne and Aix-la-Chapelle, and at Zwiefalten Einsiedeln, were the principal restors.

In Italy the church of the Archangel on Mt. Gargano was one of the most ancient centres of the pilgrimage, being visited even by the monk Bernard (side supra). Later the Porticulura church at Assisi displaced all other religious resorts, with the exception of Rome; but in the 15th century it was overshadowed in turn by the "Holy House" at Loreto in the Adriatic. According to an extravagant legend, the house of Joseph and Mary in Nazareth was transported by angels, on the night of the 9th-10th of May 1291 to Dalmatia, then brought to the Italian coast opposite (Dec. 10, 1394), till, on the 7th of September 1295 it found rest on its present site. The pilgrimage thither must have attained great importance as early as the 16th century; for the popes of the Renaissance found themselves constrained to erect an imposing church above the "Holy House.

The significance of the pilgrimage for the religious life of later medievalism cannot be adequately estimated. The possession of an extraordinary relic, a bloody Host, or the like, was everywhere considered a sufficient claim for the privileges of indulgences; and wherever this privilege existed, there the pilgrims were gathered together. All these pilgrimages, great and small, were approved and encouraged by the Church. And yet, during the whole of the middle ages, the voice of suspicion in their regard was never entirely stilled. Earnest men could not disguise from themselves the moral dangers almost inevitably consequent upon them; they recognized, moreover, that many pilgrims were actuated by extremely dubious motives; and they distrusted the exaggerated value set on outward works. The Roman papacy had no more zealous adherent than Boniface; yet he absolutely rejected the idea that Englishwomen should make the journey to Rome, and would willingly have seen the princes and bishops veto these pilgrimages altogether (Ep. 78). The theologians who surrounded Charlemagne held similar views. When the abess Ethelburga of Fladbury (Worcestershire) found her projected pilgrimage impracticable, Alcuin wrote to her, saying that it was no great loss, and that God had better designs for her: "Expend the sum thou hast gathered for the journey on the support of the poor; and if that beest as thou canst, thou shalt reap as thou wilt." (Ep. 300). Bishop Theodulf of Orleans (d. 821) made an energetic protest against the delusion that to go to Rome availed more than to live an upright life (Carm. 67). To the same effect, the synod of Chalon-sur-Saône (813) reprobated the superstition which was wedded to the pilgrimage (c. 13); and it would be easy to collect similar judgments, delivered in every centre of medievalism. But, fundamentally, pilgrimages in themselves were rejected by a mere handful; the protest was not against the thing, but against its excesses. Thus Friulian, for instance, in spite of his emphatic declaration that most pilgrims returned worse than they went, himself participated in the crusade of Frederick II.

V. The Modern Pilgrimage.—The Reformation eradicated the belief in the religious value of visits to a particular locality. It is only pious memory that draws the Protestant to the sites consecrated by ecclesiastical history. On the other hand, while in the Eastern Church things have undergone little change,—the pilgrimages, in addition to the Holy Land, visiting Mt Athos and Kiev—the developments in the Roman Church show important divergences. The Year of Jubilee, in 1555, was unprecedented in its scant attendance, but the jubilees of 1575 and 1600 again saw great armies of pilgrims marching to Rome.

XXI. 26. 

609
Fresh pilgrim resorts now began to spring up, and medieval shrines, which had fallen on evil days, to emerge from their obscurity. In the 16th century we must mention the pilgrimages to the "Holy Mount" at Görrz on the Austrian coast, and to Montserrat in the Spanish province of Barcelona: in the 17th century, those to Luxemburg, Kevelaar (Gelderland), Notre Dame de Fourvière in Lyons, Heiligenberg in Bohemia, Roermond in the Netherlands, &c. The 18th century, which witnessed the religious Aufklärung, was not favourable to the pilgrimage. Enlightened bishops and princes prohibited it altogether: so, for instance, Joseph II. of Austria. Archbishop Clement Wenceslaus of Trier forbade, in 1777, the much-frequented, medieval "leaping-procession" of Echternach (duchy of Luxembourg). The progressive theologians and clergy, moreover, assumed a hostile attitude, and, in 1800, even the Curia omitted the Year of Jubilee. The 19th century, on the other hand, led to an extraordinary revival of the pilgrimage. Not only did new resorts spring into existence—e.g. La Salette in Dauphiné (1846), and more particularly Lourdes (1858) in the department of Hautes-Pyrénées—among the number enumerate a height which enables them to compete with the medieval figures. It is computed that 60,000 pilgrims were present at La Salette on the 29th of September 1847, the first anniversary of the appearance of Mary which gave rise to the shrine. The dedication of the church of Lourdes, in 1876, took place in the presence of 30 bishops, 3000 priests and 100,000 pilgrims. In 1877 the number rose to 250,000; and similar statistics are given of the German and Austrian devotional resorts. The sanctuaries of Aix-la-Chapelle are said to have been visited by 65,000 pilgrims on the 15th of July 1860; and on the following Sunday by 52,000. From 25,000 to 30,000 persons take part each year in the resuscitated "leaping-procession" at Echternach; and the annual visitants to the "Holy Mount" at Görrz are estimated at 50,000. New motives for the pilgrimage emerged in the 19th century, although the ever-increasing cultus of the Virgin Mary may be classed as such, all of the new devotional sites being dedicated to the Virgin. For the rest, the desire of acquiring indulgences maintains its influence: but doubting voices are no more heard within the pale of the Roman Catholic Church.

PILIBHIT, a town and district of British India, in the Bareilly division of the United Provinces. The town—pop. (1901), 33,490—contains the mosque of Haiz Rahmat Khan, the Rohilla chiefest, built in the second half of the 18th century. Trade is mainly in agricultural produce, and in the products of the two great terrains of Barah and Peepal.

The District of Pilibhit has an area of 1350 sq. m.; pop. (1901), 470,339, showing a decrease of 3% in the decade. Though so near the Himalayas it is entirely a plain. In its midst is the Mala swamp. The east is forest-clad, poor and unhealthy; on the other side of the Mala the land becomes more fertile. The chief river is the Sarda, and the Gumti rises in the east. The principal crops are rice, pulses, wheat and sugar-cane. Suger-refining is carried on, and sugar, wheat, rice and hemp are exported. The Lucknow-Bareilly section of the Oudh & Rohilkhand railway runs through the district, a portion of which is watered by the Rohilkhand canals.

PILLAR (O. Fr. pilier, Mod. pilier, Late Lat. pilare, from pilà, column), an upright, insulated structure of narrow width in relation to its height, which is either employed as a support for a superincumbent load of some sort or is set up for commemorative or ornamental purposes. In the first sense the word has many common applications, as to columns supporting the girders of a warehouse floor or the deckbeams of a ship, to the single central support or pedestal of a table, machine-tool, &c., and to the masses of coal which the miner leaves in certain methods of working as supports to the roof (see Coal); it is also used figuratively of persons in such phrases as a "pillar of the state." In architecture it has distinctly the second sense. The column erected by the Emperor Theodosius I. at Constantinople is known as Pompey's pillar, and the so-called columns of Trajan and Antoninus are in reality pillars, performing no structural function beyond that of carrying a statue. In India the only example is the iron pillar at Delhi, which is an extraordinary specimen of the ironworker's art considering the remote date at which it was made.

Up to the middle of the 19th century the term "pillar" was employed to designate the masses of masonry in a church, which carry the arcades, but now the term "pier" is invariably adopted in preference.

PILLAU, a seaport and watering-place of Germany, in the Prussian province of East Prussia, on the spit of sand (Nehrung) which separates the Frische Haff from the Baltic, on the north of the entrance channel, and 29 m. by rail from Königsberg. Pop. (1905), 7374. It is fortified and has a harbour, which serves as the outer port of Königsberg, and to some extent also of Elbing and Braunsberg.

A new navigable channel was in 1900—1901 constructed from the Frische Haff to Pillau to Königsberg. Pillau has a school of navigation, and is a well-known pilot station. Ship-building, sail-making, fishing, and the working of amber are carried on.

Pillau is memorable as the place where Gustavus Adolphus of Sweden landed in 1626. It did not obtain civic privileges until 1725, but was fortified shortly after that date. In 1807 it offered a stout resistance to the French. By a treaty of the 24th of February 1812 it was ceded to Napoleon, but on the 6th of February in the following year it was restored to Prussia.

PILLION, a light saddle without pommel or bow, especially a pad fastened to the back of an ordinary saddle, as a seat for another person, generally a woman. Pillions were also used to support baggage. They were in common use from the 16th to the 18th centuries. The word appears to have been adapted into English from the Irish pilinn, cushion, formed from Lat. pedilis, skin. In the sense of a hat worn by a priest or doctor of divinity, "pillon" or "pylon" occurs in the 13th and 16th centuries. This is probably from Lat. pilicus, a conical felt hat of cap. Gr. πηλικός.

PILLNITZ, a village in the kingdom of Saxony, situated on the right bank of the Elbe, 5 m. above Dresden. Pop. (1905), 770. The new palace of the king of Saxony was built in 1818 on the site of a building which was destroyed by fire. The place became a residence of the electors of Saxony about 1700, and the different parts of the palace were erected at various times during the 18th century. By the convention of Pillnitz in August 1791 the emperor Leopold II. and Frederick William II., king of Prussia, agreed to take common action against any attack on the part of France; this compact may be regarded as the basis of the first coalition against that country.

See A. von Minchitz, Geschichte von Pillnitz (Dresden, 1893).

PILLORY (O. Fr. pilori, Prov. espildori, from Lat. speculatorum, a place of observation or "peep-hole"), an instrument of punishment which consisted of a wooden post and frame fixed on a platform raised several feet from the ground, behind which the culprit stood, his head and his hands being thrust through holes in the frame (as are the feet in the stocks) so as to be held fast, exposed in front of it. This frame in the more complicated forms of the instrument consisted of a perforated iron circle, which secured the heads and hands of several persons at the same time, but it was commonly capable of holding only one.

In the statutes of Edward I. it is enacted that every pillory or "stretch-neck" should be made of convenient strength so that captives might be burnt on offenders without peril of their bodies. It was customary to shave the heads wholly or partially, and the beards of men, and to cut off the hair and even in extreme cases to shave the heads of female culprits. Some of the offences punished in England by the pillory will be found enumerated in
a statute of Henry III. (1266). By this “Statute of the Pillory” it was ordered as the penalty for “foresters and regnators, users of deceitful weights, perjurers and forgers.” Stow, describing Cornhill pillory, says: “On the top of the cage (a strong prison of timber) was placed a pillory for the punishment of bakers offending in the assize of bread, for millers stealing corn at the mill, for bawds, scolds and other offenders.” Until 1637 the latter kind is the only one to which the term is now applied either in British or foreign countries. The word “pillor” is not the early name for the man who guides or steers a ship. In Old English the name is lādman, i.e. the man who leads the way. “Pilot” does not appear in English till the 17th century. The origin of the word has been much debated. Many etymologists find it in the Dutch pijlōt (Hieham’s Dictionary, 1638). This has been identified with pilōw, pilī-loth, sounding lead, cf. German peilen, to sound; the last part of these words is the same as English “lead,” the metal; the first part, peilen, is for pegden, to mark with pegs or points for measuring, cf. pegel, gauge. The New English Dictionary, on the other hand, finds that the Dutch pijlōt, the earlier form, is taken from the French. The source is, therefore, to be looked for in Romance languages. Du Cange (Gloss. Med. et Inf. Lat.) gives Pedota, defined as quorum est scire intrare et everti portus, a gloss on pedote e timoreni in F. Ubaldini’s edition, 1640, of I documenti d’amore by Francesco da Barberino (1264–1348). It is therefore conjectured that the Italian pilota is a popular conception of pedota, and a possible source may be found in the Greek τιθω, oar.

In England, formerly, pilots were subject to the jurisdiction of the lord high admiral; and in the 16th century there are many instances of the admiralty court dealing with pilots discriminatorily as well as civilly, holding them liable in damages to owners of ships lost or damaged by their negligence. For some considerable time throughout the United Kingdom the appointment and control of pilots have been in the hands of numerous societies or corporations established at the various ports by charter or act of Parliament, such as the Trinity Houses of Deptford Strond (London), Kingston-upon-Hull, Newcastle-on-Tyne, and Leith, and the Society of Cinque Ports Pilots and Court of Ledomanage (now extinct). These societies had jurisdiction over the pilots exercising their employment within the limits of such ports, and in many cases made it compulsory for ships resorting thither to employ them. By degrees the London Trinity House acquired a leading position, which was confirmed and extended by the general Pilotage Acts passed in the 18th and 19th centuries, with the object of introducing a uniform system throughout the realm. At the present day the United Kingdom is divided into districts for the purpose of pilotage jurisdiction. The (London) Trinity House has jurisdiction over the London district, which extends from Faversham to Dungeness and across the Medway up to London and Rochester bridges; the English Channel district, comprising the sea between Dungeness and the Isle of Wight; and the Trinity outport districts, which include any pilotage districts for the appointment of pilots within which no particular provision is made by act of Parliament or charter, and the number of which is 40, all English and Welsh. There are 66 other districts, within which other pilotage authorities have jurisdiction.

The present general pilotage law is contained in the Merchant Shipping Acts 1894 to 1906. Pilotage authorities are defined as bodies or persons appointed to authorize or license pilots, or to fix and alter rates to be paid to pilots or to exercise any jurisdiction in respect of pilotage. They are subject to the control of the Board of Trade as the supreme mercantile marine authority. Those bodies, however, which existed at the time of the passing of the act retain their powers and jurisdiction, so far as is consistent with it. The board has power to appoint a new pilotage authority in any area where there is none, and to include a new area where there is none within an already existing one (but in either case pilotage cannot be made compulsory), or to transfer pilotage jurisdiction over a port other than that where the pilotage authority for that port resides, from that pilotage authority to the Ledomanage other local authority for that port, or to the Trinity House, or to a new authority; and the board has all powers necessary to effectuate such transfer and constitute the new authority. The board may also, by provisional order (which requires parliamentary confirmation), provide for the representation of pilots or shipowners on the pilotage authority
of any district, and the exemption of ships from compulsory pilotage in any district. Where pilotage is not compulsory, and the power of obtaining pilotage licences unrestricted, the board can in the same way give the pilotage authority powers with respect to licences, amount of pilotage rates, and the like. Pilotage authorities may, by by-laws under the Act (which require confirmation by order of the Lords of the Treasury), exempt in whole or in part any ships or classes of ships from compulsory pilotage, and regulate the means of obtaining licences, and the amount of pilotage rates, subject to a maximum limit. They must make yearly returns to the Board of Trade of their by-laws, the names, ages and services of their licensed pilots, the rates of pilotage, the amounts received for pilotage and their receipts and expenditure; and if they fail to do so, the board may suspend their authority, which is then exercised by the Trinity House.

The statutes also provide generally for the qualifications of pilots. A "qualified" pilot is one duly licensed by a pilotage authority to conduct ships to which he does not belong.

Qualifications.

On his appointment he receives a licence, which is registered with the chief officer of customs at the nearest place to the pilot's residence, and must be delivered up by the pilot whenever required by the licensing pilotage authority. On his death this licence must be returned to that authority. By an act of 1906 no pilotage certificate shall be granted to the master or mate of a British ship unless he is a British subject; this does not, however, refer to the renewal of a certificate granted before 1906 to one not a British subject. Pilotage dues are recoverable summarily from the owner, master, or consignees of the ship, after a written demand for them has been made. A pilot may not be taken beyond the limits of his district without his consent, and if so taken he is entitled to a fixed daily sum in addition to the dues; if he cannot board the ship, and leads her from his boat, he is entitled to the same dues as if he were on board; and he must be truly informed of the ship's draught of water. An unqualified pilot may in any pilotage district take charge of a ship without subjecting himself or his employer to any penalty, where no qualified pilot has offered himself, or where a ship is in distress, or in circumstances where the master must take the best assistance he can, or for the purpose of changing the moorings of any ship in port or docking or undocking her; but after a qualified pilot has offered himself any unqualified pilot continuing to hold or be in charge of the ship is liable to a penalty. A qualified pilot may not be directly or indirectly interested in licensed premises or in the selling of dutiable goods, or in the unnecessary supply of gear or stores to a ship for his personal gain or for the gain of any other person. He can be punished for quitting a ship before the completion of his duty without the consent of the master, refusing or delaying to perform his duty without reasonable cause when required by lawful authority, lending his licence, acting as pilot when suspended or when intoxicated, and any pilot who through wilful breach of or neglect of duty, or by reason of his drunkenness, endangers ship, life or limb, is guilty of a misdemeanour and liable to suspension or dismissal; but the pilot has an appeal in cases of fines over £2, of suspension or dismissal, suspension or revocation of his licence, or the application of a pilotage fund to which he has contributed. This appeal lies in England to a county court judge having jurisdiction over the port where he is licensed, or a metropolitan police magistrate or stipendiary magistrate with the like power; in Scotland, to a sheriff; in Ireland, to a county court judge, chairman of quarter sessions, recorder, or magistrate. Pilotage certificates may also be granted by pilotage authorities, available within their districts, to masters and mates of ships; and the holder of such a certificate may pilot any ship in respect of which it is available without incurring any penalty for failing to comply with the Act.

The statute further makes special regulation for Trinity House pilots. Every such pilot, on his appointment, must execute a bond for £200 conditioned for due observance of the Trinity House regulations and by-laws, and thereupon he is not liable for neglect or want of skill to anybody beyond the penalty of the bond and the amount payable to him for pilotage on the voyage on which he was engaged at the time of his so becoming liable. The licence may be revoked or suspended by the Trinity House when it thinks fit; it only continues in force for a year, and the Trinity House has absolute discretion whether it shall be renewed or not.

A pilot boat is approved and licensed by the district pilotage authority who appoints or removes the master thereof. In order to be easily recognized, she has printed on her stern in legible white letters the name of her owner and her port, and on her bows the number of her licence; the remainder of the boat is usually black. The pilot flag is a red and white horizontal flag of a comparatively large size, and is flown from a conspicuous position. When the flag is flown from a merchant vessel, it indicates that a licensed pilot is on board or that the master or mate holds a certificate entitled him to pilot the ship. By order in council of 1900, on and after the 1st day of January 1901 the signals for a pilot displayed together or separately are: In daytime, there is (1) hoisted at the fore the pilot jack (Union Jack having round it a white border, one-fifth of the breadth of the flag); (2) the international code pilotage signal indicated by P.T.; (3) the international code flag S. (white with small blue square centre), with or without the code pennant; (4) the distant signal consisting of a cone point upwards, having above it two balls or shapes resembling balls. By night, (1) the pyrotechnic light commonly known as a blue light, every fifteen seconds; (2) a bright white light, flashed or shown at short or frequent intervals just above the bulwarks, for about a minute at a time.

Pilotage in British waters may be either compulsory or free for all or certain classes of ships. From parliamentary pilotage returns, it appears that it is compulsory in about 64 districts of the United Kingdom (of which two-thirds are the Trinity House districts), free in 32, free and compulsory in 8, while in 3 cases (Berwick, Dingwall and Coleraine) no particulars are given. British war-ships in British waters are not compelled to employ a pilot, the navigating officer becoming the pilot under the direction of the captain. If a pilot be employed, the captain and navigating officer are not relieved from responsibility. They supervise the pilot, and should, if necessary, remove him from the ship. In the majority of foreign ports British war-ships are exempted from employing pilots, but the Suez Canal and the ports of France are exceptions. The Merchant Shipping Act 1894 continues the compulsory employment of pilots in all districts where it was already compulsory, and also the already existing exceptions; and there is no power in any pilotage authority or the Board of Trade to increase the area of compulsory pilotage, though there is to diminish it. Compulsion is enforced by a provision in the act, that within a district where compulsory pilotage exists, the master of an unexempted ship who pilots her himself without holding the necessary certificate, after a qualified pilot has offered or signalled to take charge of the ship, shall be liable for each offence to a fine of double the amount of the pilotage dues demandable for the conduct of the ship. The exemptions from compulsory pilotage still existing in British waters are as follows: Ships or vessels with British registers trading to Norway or the Cattegat or the Baltic (except vessels on voyages between any port in Sweden or Norway and the port of London), or round the North Cape, or into the White Sea on their inward or outward voyages, whether coming up by North or South Channels; any constant British traders inwards from ports between Boulogne inclusive and the Baltic coming up by North Channel, and any British ships or vessels trading to ports within the limits of their outward passages and when coming up by the South Channels; Irish traders using the navigation of the Thames and Medway; ships engaged in the regular or masterly trade of the king's ships or vessels wholly laden with stone produced in the Channel Islands and Isle of Man and thence; ships or vessels not exceeding 60 tons, whether British or belonging to a foreign country specified by order in council; ships within the limits of the port or place to which they belong, if
this is not a place particularly provided for by act of Parliament or charter as regards the appointment of pilots; ships passing through the limits of any pilotage district in their voyages from one port to another port, and not being bound to any port or place within such limits or anchoring therein, but not including ships navigating at any place situable within the district, or at any place situated above the district on the same river or its tributaries. Ships whose masters or mates are owners or part-owners of them, and living at Dover, Deal, or the Isle of Thanet, may be piloted by them from any of these places up and down the Thames or Medway, or into or out of any place or port within the jurisdiction of the Cinque Ports. The following ships in the London district and Trinity outport districts are also exempt when not carrying passengers, namely: Ships employed in the coasting trade of the United Kingdom; ships of not more than 60 tons burden; ships trading to or from any port in Great Britain within the above districts or from the port of Brest in France, and any port in Europe (which does not include the United Kingdom) north and east of Brest, or to the Channel Islands or Isle of Man; and ships navigating within the limits of the port to which they belong. The port to or from which the ship must be "trading" in this provision has been interpreted by the decisions to mean the port where the cargo is substantially discharged or loaded respectively; and the word "coaster" similarly has been held to apply only to a vessel carrying to one port of the United Kingdom a cargo which has been taken in at another. Every ship carrying passengers between any place in the British Islands and any other place so situate must carry a compulsory pilot, unless her master or mate have a pilotage certificate. The effect in law of the ship (British or foreign) being in charge of a compulsory pilot under the act is that her owner and master are not answerable to any person whatever for any loss or damage occasioned by the fault or incapacity of any qualified pilot acting in charge of such ship within any district where the employment of such pilot is compulsory by law. In order to take advantage of this privilege, the shipowner must show (1) that a properly qualified pilot was acting in charge of the ship; there are, however, various kinds of qualified pilots—the qualified pilot who is always capable of acting, and the qualified pilot who is liable to be superseded if a better can be obtained; (2) that that charge was compulsory; the pilot, however, is not necessarily to be compulsorily employed at the place where the accident happened, so long as he is compulsorily employed within the district where it happens; (3) that it was the sole pilot's fault or incapacity which caused the damage. Similarly, under the Harbours, Piers and Docks Clauses Act, the owner of a vessel is not liable for damage done thereby to docks or piers when she is in charge of a duly licensed pilot.

This statutory exemption of a ship in charge of a compulsory pilot from any liability for her negligent navigation by that pilot, is only declaratory of the common law of England, and is based on the principle that the pilot is a state official put in charge of a ship, and is not the servant of the shipowner so as to make him liable for his negligence; and a British court gives the same effect to any foreign or colonial law which makes it compulsory on shipowners to put a pilot in charge of their ship when within their jurisdiction. Most foreign codes, however, while agreeing with English law in making the presence of a pilot on board compulsory, differ from it in not putting him in charge of the ship; and in this case the defence of compulsory pilotage cannot be pleaded successfully in British courts. Judicial decisions have established that French, Suez Canal, Danube and Dutch pilots are not compulsory pilots in the British sense of the word, being only advisers of the master, or "living charts." But if the pilot is put in charge by the foreign port authority that in spite of the owner surrendering the charge of the ship to him the owner shall still remain liable, a British court will hold the owner free from liability, on the ground that to make any person liable for a tort committed abroad, the act complained of must be wrong not only according to the foreign law, but also by English law. This consequence which English law attaches to the employment of a compulsory pilot has been much criticized in recent times, and it would seem that the foreign view is much more satisfactory in regarding the pilot merely as the adviser and not the superior of the master. Moreover, the adoption of the foreign law on this point would restore the old general maritime law. The policy of the law was at one time inclined to extend this principle of compulsory pilotage on the ground that it was for the benefit of commerce and the safety of seamen's lives, but it now restricts it within as narrow limits as possible, e.g. the presence of a compulsory pilot on board a tug who is directing the navigation of a tug does not protect the tug-owner from liability for negligent navigation. As already pointed out, pilotage authorities have no power to extend its scope.

A pilot who is compulsorily in charge of a ship under English law has supreme control over her navigation, superseding the master for the time being; and if she is a tow he has also control of the navigation of her tug. The judicial decisions establish that it is within his province to decide whether the ship shall get under way, the proper time and place for her to anchor, the way of carrying her anchor, the proper orders for the helm, her rate of speed, and whether the statutory rules of navigation shall be complied with; and the master and crew must not interfere with his control, and only remain liable for the proper execution of the pilot's orders and the trim and general efficiency as to look-out, &c., of the ship. The master, however, is bound to supersede the pilot in case of his intoxication or manifest incapacity, and to interfere if there is a clear and plain prospect of danger to the ship in following the pilot's directions, e.g. getting under way in a thick fog. The pilot is entitled to receive from the master assistance in having his attention called to anything which a competent mariner would see that he ought to know. A pilot taken voluntarily, and not by compulsion of law, is considered as the servant of the shipowner, and as such renders him liable for his acts of negligence towards third parties. He does not, it seems, supersede the master in the control of the ship, but only advises him. The Admiralty and the Board of Trade and the Trinity House all take the view that the captain or master is bound to keep a vigilant eye on the navigation of the vessel by the pilot, and insist on all proper precautions being taken. For the purposes of a policy of marine insurance a ship is not seaworthy without a pilot in compulsory pilotage waters; and where there is no legal compulsion to have one, but the locality requires navigation by a person having local knowledge, it has been said that a ship must take a pilot, certainly when leaving a port, and probably on entering a port if a pilot is available.

A pilot can sue for his pilotage fee at common law or in Admiralty (q.v.), in the latter case provided that the contract was made and the work done not within the body of a county; but he has a summary remedy by statute which is of easier application. He cannot be sued in Admiralty for damage done by a collision caused by his negligence (e.g. on the Admiralty side of a county court having Admiralty jurisdiction); but he can be made liable at common law or in the Admiralty Division of the High Court, although in the case of a Trinity House pilot his liability is limited to the amount of his bond and pilotage fee then being earned (see above); but the court has refused to join him as a defendant to an action in rem brought against the ship of which he had the charge. A pilotage authority cannot be made liable for the negligent navigation of a ship by a pilot which it has licensed, for he is not its servant, though it has been held liable for the negligence of a person not licensed by it as a pilot, but employed by it for wages to pilot ships into a harbour under its jurisdiction, itself taking the pilotage dues and applying them for harbour purposes. A pilot is not in common employment with the master and crew of a ship, and can recover for any injury done him by their negligence. He may be entitled to claim salvage from a ship of which he has charge, if the services he renders are beyond the scope of his pilotage contract, either from the outset or owing to supervening circumstances, but not otherwise, whether he is on board her or leading her from his boat. (See Salvage.)

In the United States pilotage laws are regulated by the respective
states. If the waters are the boundary between two states a duly licensed pilot of either state may be employed, but no dis- 
crimination can be made in the rates of piloting between vessels 
of different states. In the German Empire the piloting laws 
are very complicated. In the majority of the maritime states 
each one has its own regulations and laws. In Prussia there are 
government pilots who enter the service as apprentices, and are 
placed under a department of state. In France the general organi-
zation of pilots is regulated by the Statute on Pilots of the 12th 
of December 1866, and the piloting regulations for each port are 
made by the minister of marine at the request of his local rep- 
resentative and the Chamber of Commerce. French pilots are 
exempt from military service.

1910); *Select Pleas of the Admiralty* (Selden Society, London, 
1892 and 1897); Temperley, *Merchant Shipping Acts* (1907); *The 

**PILOT-FISH** (*Naucrates ductor*), a pelagic fish of the family 
of horse-mackerels or *Carangidae*, well known to sailors from 
its peculiar habit of keeping company with ships and large fishes, 
especially sharks. It occurs in all tropical and sub-tropical 
seas, and is common in the Mediterranean, but becomes scarcer 
in higher latitudes. In summer pilots will accompany ships 
as far north as the south coast of England into port. This 
habit was known to the ancients, who describe the *Pomiphus* as 
a fish which points out the way to dubious or embarrassed 
sailors, and by its sudden disappearance indicates to them the 
vicinity of land; the ancient seamen of the Mediterranean re-
garded it, therefore, as a sacred fish. That the pilot accompanies 
sharks is an observation which first appears in works of travel 
of the 17th century, the writers asserting that it is of great use 
to its big companion in conducting it and showing it the way to 
itself. It is, however, extremely doubtful whether the pilot's 
connexion with a shark serves a more special purpose than its 
temporary attachment to a ship. It accompanies both on account 
of the supply of food which it derives from them. The pilot, 
therefore, stands to both in the relation of a so-called "com-
mensal," like the *Echeneis* or sucking-fish. All observers, 
evertheless, agree that neither the pilot nor the sucker is ever 
attacked by the shark. The pilot attains to a length of about 
12 in. In the shape of its body it resembles a mackerel, but is rather shorter, especially in the head, and covered with 
small scales. A sharp keel runs along the middle of each side of 
the tail. The first dorsal fin consists of a few short spines not 
connected by a membrane; the second dorsal and the anal are 
composed of numerous rays. The teeth, which occupy the jaws, 
vomer and palatine bones, are all small, in villiform bands. 
The coloration of the pilot renders it conspicuous at a distance; 
on a bluish ground-colour from five to seven dark-blue or violet 
cross-bands traverse the body from the back to the belly. The 
pilot-fish spends in the open sea, and its fry is constantly caught 
in the tow-net. But young pilot-fish differ considerably from 
the adult, having the spines of the first dorsal connected by a 
membrane, and some bones of the head armed with projecting 
spines. These little fishes were therefore long regarded to be 
a distinct genus, *Naucerus*.

**PILOTY, KARL VON** (1826-1886), German painter, was born 
at Munich, on the 1st of October 1826. His father, Ferdinand 
Piloty (d. 1844), enjoyed a great repute as a lithographer. In 
1840 he was admitted as a student of the Munich Academy, 
under the artists Schorn and Schnorr. After a journey to 
Belgium, France and England, he commenced work as a painter of 
gene pictures, and in 1853 produced a work, *Die Almme* ("The Wet Nurse"), which, on account of its originality of style, 
caused a considerable sensation in Germany at the time. But 
he soon forsook this branch of painting in favour of historical 
subjects, and produced in 1854 for King Maximilian II. "The 
Adhesion of France to Maximilian of the Old League in 1669." 
It was succeeded by "Seni at the Dead Body of Wallenstein" 
(1855), which gained for the young painter the membership of 
the Munich Academy, where he succeeded Schorn (his brother-in-
law) as professor. Among other well-known works by Piloty 
are the "Battle of the White Mountain near Prague," "Nero 
Dancing upon the Ruins of Rome" (1867), "Godfrey of Bouillon 

PILOT-FISH—PIMENTO

on a Pilgrimage to the Holy Land" (1861), "Galileo in Prison" 
(1864), and "The Death of Alexander the Great" (unfinished), 
his last great work. He also executed a number of mural paint-
ings for the royal palace in Munich. For Baron von Schach he 
painted the justly celebrated "Dissolution of America." In 1874 
he was appointed keeper of the Munich Academy, but afterwards 
enshiled by the king of Bavaria. Piloty was the fore-
mest representative of the realistic school in Germany. He was 
a most successful teacher, and among his more famous pupils 
may be mentioned Makart, Lenbach, Defregger, Max and 
Grützner. He died at Munich on the 21st of July 1886.

**PILSEN** (Czech, *Pilsen*), a town of Bohemia, Austria, 68 m. 
W.S.W. of Prague by rail. Pop. (1900), 68,392, of which 94% 
are Czech. It is the second town of Bohemia, and lies at 
the confluence of the Radbuza and the M统计局. It consists of the 
town proper, which is regularly built and surrounded with 
parapets on the site of the old ramparts, and of three suburbs. 
The most prominent buildings are the Gothic church of St 
Bartholomew, said to date from 1202, whose tower (325 ft) is 
the highest in Bohemia, and the fine Renaissance town hall 
dating from the 16th century. The staple article of manufacture 
and commerce is beer, which is exported to all parts of the world. 
Other industrial products are machinery, enamelled theware, 
leather, alum, paper, cartheware, stoves and spirits, while a 
tolerably brisk trade is carried on in wool, leathers, cattle 
and horses. In the neighbourhood are several coal-pits, iron-works 
and glass-works, as well as large deposits of kaolin.

Pilsen first appears in history in 976, as the scene of a battle 
in the war between Prince Boleslaus and the emperor Otto II., 
and it became a town in 1272. During the Hussite wars it was 
the centre of Catholic resistance to the Hussites; it was three 
times unsuccessfully besieged by Prokot the Great, and it took 
part in the league of the Romanist lords against King George 
of Podebrad. During the Thirty Years' War the town was taken 
by Mansfeld in 1618 and not recaptured by the Imperialists till 
1621. Wallenstein made it his winter-quarters in 1633, and it 
was in the great hall of the *Rathaus* that his generals took 
the oath of fidelity to him (January 1634). The town was unsuccess-
fully besieged by the Swedes in 1637 and 1649. The first 
Bohemian printing press was established here in 1485.

**PIMA**, a tribe and stock of North American Indians. Their 
range was southern Arizona and northern Mexico. The ruined 
Pima village, known to the Spaniard as Casa Grande on the south 
bank of the Gila, is an example of their early civilization and skill 
in building. Driven out of their homes by neighbouring tribes, 
they lived a more or less nomadic life. They were always good 
farmers, showing much skill in irrigation. At first submitting 
to the Spaniards, they revolted in 1751, destroying all the 
missions. The war lasted two years, but since then the Pima 
Indians have been friendly with the settlers. As a race they 
are brave, honest and hard working. They number some 5000 on 
two reservations in Arizona. The Piman stock includes such 
tribes as the Papago, Huchchel, Opata, Tarumari, and numbers 
upwards of a hundred thousand.

**PIMENTO**, also called *Allspice* (from a supposed combina-
tion of various flavours) and *Jamaica Pepper*, the dried immature 
fruit of *Eugenia pimenta* or *Pimenta officinalis*, an evergreen tree 
about 30 ft. high, belonging to the natural order *Myrtaceae*. 
It is indigenous in the West India Islands, growing on limestone 
hills near the sea, and is especially grown in Jamaica. The spice 
derives its name from the Portuguese *pimenta*, *Spanish pimienta*, 
pepper, which was given to it from its resemblance to
pepper-corns. The berries are gathered in July and August, when of full size, but still unripe—the small branches bearing fruit being broken off and dried in the sun and air for some days, when the stalk is broken off and the berries are ready for picking. These owe their aromatic properties to an essential oil present to the extent of 3 to 4½% and consisting largely of eugenol or allyl guaiacol, HO(C₆H₄O)CH₃-C₆H₅. The chief use of pimento is as a spice. The oil, the action of which resembles that of cloves, is occasionally used in medicine, and is also employed in perfuming soaps.

PIN (a doublet with "pen" from Lat. pinna, feather, pinnacle, which is said to contain the same root as strus, pine tree, and probably to mean a sharp point or a small spike. These pins are of metal or wood, not necessarily pointed, employed as a fastening to connect together different parts of an article, as a stop to limit the motion of some moving piece in a machine, as a support on which a small wheel may turn, &c., but most commonly a small metal spike, used for fastening portions of fabrics together, having one end pointed and at the other a bulbed head, or some other arrangement for preventing the spike from passing entirely through the cloth or other material with which it is employed. In one form or another pins of this kind are of the highest antiquity, the earliest form doubtless being a natural thorn. Pins of bronze, and bronze brass in which the pin was formed, are often found with the remains of the bronze age. The ordinary domestic pin had become in the 15th century an article of sufficient importance in England to warrant legislative notice, as in 1483 the importation of pins was prohibited by statute. In 1540 Queen Catherine received pins from France, and again in 1543 an act was passed providing that "no person shall put to sale any pinnes but only such as shall be double headed, and have the heads soldered fast to the shank of the pinnes, well smoothed, the shank well shapen, the points well and round filed, canted and sharpened." At that time pins of good quality were made of brass; but a large proportion of those against which the legislative enactment was directed were made of iron wire blanched and passed as brass pins. To a large extent the supply of pins in England was received from France till about 1626, in which year the manufacture was introduced into Gloucestershire by John Tilsley. His business flourished so well that he soon gave employment to 1500 persons, and Stroud pins attained a high reputation. In 1636 the pinmakers of London formed a corporation, and the manufacture was subsequently established at Bristol and Birmingham, the latter town ultimately becoming the principal centre of the industry. So early as 1775 the attention of the enterprise colonists in Carolina was drawn to the manufacture by the offer of prizes for the first native-made pins and needles. At a later date several pin-making machines were invented in the United States. During the war of 1812, when the price of pins rose enormously, the manufacture was actually started, but the industry was not fairly successful till about the year 1836 when the Howe Manufacturing Company was formed at Birmingham, Connecticut. Previous to this an American, Lemuel W. Wright, had in 1824 secured in England a patent for a machine to make solid-headed pins, which established the industry on its present basis.

The old form of pin consisted of a shank with a separate head of fine wire twisted round and secured to it. Fine wire for heads was first wound on a lathe round a spit the exact circumference of the pin shanks to be headed. In this way a long elastic spiral was produced which had next to be cut into heads, each consisting of two complete loops of the spiral. These heads were softened by bending and made into a head for the heading boy, whose duty was it to thrust a number of shanks into the head and let as many as might be fit themselves with heads. Such shanks came out thus attached to the head and to the shank of the pin, which was cut off and held in a die till a globular head was formed on one end by compression, and the other end was pointed by the revolution around it of a roughened steel wheel. This machine does not seem to have come into use in this country before the pin-making apparatus above referred to as the parent form of the machinery now employed. A factory equipped with such machines was established in London, but the company which owned it was afterwards dissolved. The plant passed into the hands of F. J. Taylor of Birmingham, who obtained an extension of Wright's patent for five years from 1838, and his firm was the first to carry out the production of solid wire pins on a commercial basis. In a modern pin-making machine wire of suitable gauge running off a reel is drawn in and straightened by passing between straightening pins or studs set in a table. When a pin length has entered it is caught by lateral jaws, beyond which ends of the pin projects to form a pin-head. Against this end a steel punch advances and compresses the metal by a die arrangement into the form of a head. The pin length is immediately cut off. The pin is then passed through a set of rollers and a little sufficiently wide to pass the wire through but retain the head. The pins are consequently suspended by the head while their projecting extremities are held against revolving cutters, by which the pins are next cleaned by being boiled in weak beer, and then arranged in a copper pan in layers alternating with layers of grained tin. The contents of the pan are covered with water over which a quantity of oil is sprinkled. After many hours of this treatment the pins are passed through several baths of oil and then under oil, and finally immersed in black castor and dried in a stove. A considerable variety of pins, including the ingeniously coiled, bent and twisted, and novelty safety pin, ladies' hairpins, &c., are also produced in automatic machines. The sizes range from the 3½-in. stout blanket pin down to the finest slender gilt pin used by entomologists, 4500 of which weigh about an ounce.

PIN, RUY DE (1440-1521), Portuguese chronicler, was a native of Guarda. He acted as secretary of the embassy sent by King John II. to Castile in the spring of 1482, and in the following September returned there as sole envoy. He was present at the execution of the duke of Alba at Evora in 1483, and in 1484 went to Rome as secretary of an embassy to Pope Innocent VII. On his return, the king charged him to write a history of his reign and gave him a pension for his support. Following the arrival of Columbus from his first voyage in 1493, Pina was one of the commissaries despatched to Barcelona by John II. to negotiate with the Catholic sovereigns respecting the limits of their respective jurisdictions. In September 1495 he attested the will of John II. in his capacity as a notary public, and on the 25th of October of the same year he was present at his master's death at Alvor and opened and read his testament. King Manoel confirmed his pension and appointed him in 1497 chronicler of the kingdom, keeper of the archives and royal librarian, with a suitable salary. By 1504 Pina had completed his chronicles of Alphonso V. and John II. King John III. charged him with a history of his father, Manoel, and at his death Pina had carried it down to the capture of Azamor, as we know from Damiao de Goes, who used it in preparing his own chronicle of that monarch.

It is probable that the chronicles of the early kings of Portugal from Sancho I. to Alphonso IV. which were published under Pina's name in the 18th century were written by Fernao Lopes and edited by Pina, while that of King Duarte seems to have been published posthumously and ascribed to Pina by posterity. Pina may be the editor only. Pina was a favourite of fortune during his life, for, apart from royal benefactions, he received presents from public men who wished to figure well in his books, and after his death he obtained the credit for work that was not his. His authority as an historian is considerable, and his frankness is said to have provoked remark from contemporaries.

Pina's chronicle of King Alphonso IV. was first published in Lisbon in 1853; those of King Duarte and King Alphonso V. in vol. i. of the Coleición de livros inéditos da historia portuguesa.
PINACOTHECA, a picture-galllery (Gr. παναθήκη, from πίνας, a tablet or picture). The name is especially given to the building containing pictures which formed the left wing of the Propylæa on the Acropolis at Athens. Though Pausanias (Bk. II. xxii. 6) speaks of the pictures "which time had not effaced," which seems to point to fresco painting, the fact is there is no trace of any preparation for stucco over the walls rather than shows that the paintings were waxed cases (J. G. Frazer, Pausanias's Description of Greece, ii. 252). The Romans adopted the term for the room in a private house containing pictures, statues, and other works of art. It is used for a public gallery on the continent of Europe, as at Bologna and Turin. At Munich there are two galleries known as the Old and New Pinakothek.

PINAR DEL RIO, capital of Pinar del Rio Province, Cuba, about 107 m. S.W. by railway from Havana. Pop. (1907), 16,634. The city is in the fertile valley of the Guama. It is the centre of the tobacco industry of the Vuelta Abajo region. Its port is La Coloma, on the southern coast. The pueblo was created after 1773; but the historic settlement goes back to the public church dates from 1710.

PINKNEY, CHARLES (1757-1824), American statesman, was born on the 26th of October 1757 at Charleston, South Carolina; he was the son of Charles Pinkney (1731-1784), first president of the first South Carolina Provincial Congress (Jan. to June 1775), and a cousin of Charles Cotesworth Pinckney and Thomas Pinckney. He was studying law at the outbreak of the War of Independence, served in the early campaigns in the South, and in 1776 was elected to the South Carolina House of Representatives. He was captured by the British at the fall of Charleston (1780), and received a pardon under the close of hostilities; he was elected a delegate to the Congress of the Confederation in 1784, 1785, and 1786, and in 1786 he moved an appointment of a committee "to take into consideration the affairs of the nation," advocating in this connexion an enlargement of the powers of Congress. The committee having been appointed, Pinckney was made chairman of a sub-committee which prepared a plan for amending the articles of confederation. In 1787 he was a delegate to the Federal constitutional convention, and on the same day (May 29) on which Edmund Randolph (q.v.) presented what is known as the Virginia plan, Pinckney presented a draft of a constitution which is known as the Pinckney plan. Although Randolph resolutely opposed Pinckney's plan, he considered that the new constitution was framed, Pinckney's plan seems to have been much drawn upon. Furthermore, Pinckney appears to have made valuable suggestions regarding phrasing and matters of detail. On the 18th of August he introduced a series of resolutions, and to him should probably be accredited the authorship of some thirty-one or thirty-two provisions of the constitution. 1

1 The "Pinckney Plan" has been the subject of considerable discussion. When, in 1818, John Quincy Adams was preparing the journal of the convention for publication and discovered that the Pinckney plan was missing, he wrote to Pinckney for a copy, and Pinckney sent him what he asserted was either a copy of his original draft or a copy of a draft which differed from the original in no particular. This was either a copy of a draft presented to the committee of detail, Madison and others, who had been members of the convention, as well as historians, treated it as a spurious, and for years Pinckney received little credit for his work in the convention. Later historians, however, notably J. Franklin Jameson and Andrew C. McLaughlin, have accredited to him the suggestion of a number of provisions of the constitution as a result of their efforts to reconstruct his original plan chiefly from his speeches, or alleged speeches. Among his adherents was James Wilson, a member of the committee of detail, one of whose papers is believed to be an outline of the Pinckney plan. See J. F. Jameson, "Studies in the History of the Federal Convention of 1787," in the Annual Report of the American Historical Association for 1902, vol. i.; A. C. McLaughlin, "Outline of Pinckney's Plan for a Constitution," in The Nation, April 28, 1903; an article entitled Sketch of Pinckney's Plan for a Constitution, in the American Historical Review for July 1903; and C. C. Not, The Mystery of the Pinckney Draft (New York, 1908), an attempt by a former chief-justice of the U.S. Court of Claims to prove that

ney was president of the State Convention of 1790 that framed a new constitution for South Carolina, was governor of the state from 1790 to 1792, a member of the House of Representatives in 1792-1796, and again governor from 1796 to 1798. From 1799 to 1801 he was a member of the United States Senate. He entered public life as a Federalist, but later became the leader in organizing the Democratic-Republican party in his state, and contributed largely to the success of Thomas Jefferson in the presidential election of 1800. By Jefferson's appointment he was American minister to Spain from 1801 to 1805. In general his mission was a distinct failure, his arrogance and dogmatism alienating the Spanish government to request his recall. He was elected to the state House of Representatives in 1805, was again governor of South Carolina from 1806 to 1808, in 1810-1814 was once more a member of the state House of Representatives, in which he defended President Madison's war policy, and from 1819 to 1821 was a member of the National House of Representatives, in which he opposed the Missouri Compromise in a brilliant speech. He died at Charleston, South Carolina, on the 20th of October 1824.

His son, HENRY LAURENS PINCKNEY (1794-1863), was a member of the South Carolina House of Representatives in 1816-1832, in 1819 and edited for fifteen years the Charleston Mercury, the principal exponent of state's rights principles, and was a member of the National House of Representatives in 1833-1837.

PINKNEY, CHARLES COTESWORTH (1746-1825), American statesman, was born in Charleston, South Carolina, on the 25th of February 1746, the son of Charles Pinckney (d. 1758), 2 by his second wife, the celebrated girl planter, Eliza Lucas. When a child he was sent to England, like his brother Thomas after him, to be educated. Both of them were at Westminster and Oxford and were called to the bar, and for a time they studied in France at the Royal Military College at Caen. Returning to America in 1769, C. C. Pinckney began the practice of law at Charleston, and soon became the exponent of the rights of the people against the authority of the central government. He was a member of the South Carolina provincial congress in 1775, served as colonel in the South Carolina militia in 1776-1777, was chosen president of the South Carolina Senate in 1779, took part in the Georgia expedition and the attack on Savannah in the same year, was captured at the fall of Charleston in 1780 and was kept in close confinement until 1782, when he was exchanged. In 1783 he was commissioned a brevet brigadier-general in the continental army. He was an influential member of the constitutional convention of 1787, advocating the counting of all slaves as a basis of representation and opposing the abolition of the slave-trade. He opposed as "impracticable the election of representatives by a popular election of senators, who, he thought, should be men of wealth. Subsequently Pinckney bore a prominent part in securing the ratification of the Federal constitution in the South Carolina convention called for that purpose in 1788 and in framing the South Carolina State Constitution in the convention of 1790. After the organization of the Federal government, President Washington offered him at different times appointments as associate justice of the Supreme Court (1791), secretary of war (1795) and secretary the document sent by Pinckney to Adams in 1818 is a genuine copy of his original. He was an ardent supporter of the British army, who about 1738 removed from Antigua to South Carolina, where he acquired several plantations. He was almost immediately recalled to Antigua, and his daughter under- took the management of the plantations. He was conspicuous in his service, and is said to have been the first to introduce into South Carolina (and into continental North Carolina) the cultivation and manufacture of indigo, and he also imported silk-worms—in 1753 she presented to the princess of Wales a dress made of Carolina silkworms. She was married to Charles Pinckney in 1744. See Harriott H. Ravenel, Eliza Pinckney (New York, 1896), in the "Women of Colonial and Revolutionary Times" series.
of state (1795), each of which he declined; but in 1796 he succeeded James Monroe as minister to France. The Directory refused to receive him, and he retired to Holland, but in the next year, Elbridge Gerry and John Marshall having been appointed to act with him, he again repaired to Paris, where he is said to have made the famous reply to a verdict demanding a loan of $1,000,000,000 in reality for a gift," "Millions for defense, and millions more for tribute," another version is, "No, not a sixpence." The mission accomplished nothing, and Pinckney and Marshall left France in disgust, Gerry (q.v.) remaining. When the correspondence of the commissioners was sent to the United States Congress the letters "X," "Y," and "Z," were inserted in place of the names of the French agents with whom the commission treated—hence the "X Y Z Correspondence," famous in American history. In 1800 he was the Federalist candidate for vice-president, and in 1804 and again in 1808 for president, receiving 14 electoral votes in the former and 47 in the latter. From 1805 until his death, on the 16th of August 1825, he was president-general of the Society of the Cincinnati.

PINDAR, Thomas (1750-1828), American statesman and diplomat, was born in Charleston, South Carolina, on the 23rd of October 1750, a younger brother of Charles Cotesworth Pinckney (q.v.). Educated in England, he returned to Charleston in 1773, and was admitted to the bar in 1774. During the War of Independence his early training at the French military college at Caen enabled him to render effective service to General Benjamin Lincoln in 1778-1779, to Count d'Estaing (1779), to General Lincoln in the defence of Charleston and afterwards to General Horatio Gates. In the battle of Camden he was badly wounded and captured, remaining a prisoner for more than a year. Subsequently he was governor of South Carolina in 1787-1789; presided over the state convention which ratified the Federal constitution in 1788; was a member of the state legislature in 1791; and was United States minister to Great Britain in 1792-1796. During part of this time (1794-1795) he was also envoy extraordinary to Spain, and in this capacity negotiated (1795) the important Treaty of San Lorenzo el Real; by that treaty the boundary between the United States and East and West Florida and between the United States and "Louisiana" was settled (Spain relinquishing all claims east of the Mississippi above 36° N. lat.), and the United States secured the freedom of navigation of the Mississippi to its mouth with the right of deposit at New Orleans for three years, after which the United States was to have the same right either at New Orleans or at some other place on the Mississippi to be designated by Spain. In 1796 Pinckney was the Federalist candidate for vice-president, and in 1797-1801 he was a Federalist representative in Congress. During the War of 1812 he was a major-general. In 1825 he succeeded his brother as president-general of the Society of the Cincinnati. He died in Charleston on the 2nd of November 1828. Pinckney, like many other South Carolina revolutionary leaders, was of aristocratic birth and politics, closely connected with England by ties of blood, education and business relations. This renders the more remarkable their attitude in the War of Independence, for which they made great sacrifices. Men of Pinckney's type were not in sympathy with the progressive democratic spirit of America, and they began to withdraw from politics after about 1800.

See C. C. Pinckney, Life of General Thomas Pinckney (Boston, 1895).

PINDAR (Gr. Πίνδαρος, c. 522-443 B.C.), the great lyric poet of ancient Greece, was born at Cynoscophepha, in Boeotia, at the time of the Pythian games (fr. 175, Bergk 4, 193), which is taken by Böckh to be 522 B.C. He would thus be some thirty-four years younger than Simonides of Ceos. He was the son of Daiphantus and Cleodice (or Cedicle). The traditions of his family have left their impress on his poetry, and are not without some value for correct estimate of his relation to his contemporaries. The clan of the Aegidae—tracing their line from the hero Aegeus—belonged to the "Cadmean" element of Thebes, i.e. to the elder nobility whose supposed date went back to the days of the founder Cadmus. A branch of the Theban Aegidae had been settled in Achaean times at Amyclae in the valley of the Eurotas (Pind. Isthm. vi. 14), and after the Dorian conquest of the Peloponnesus had been apparently adopted by the Spartans into one of the three Dorian tribes. Pindar's father, Aegisthion, colonized the island of Thera (Pyth. vi. 68-70). Another branch of the race was settled at Cyrene in Africa; and Pindar tells how his Aegid clansmen at Thebes "showed honour" to Cyrene as often as they kept the festival of the Carnea (Pyth. v. 73). Pindar is to be conceived, then, as standing within the circle of those families for whom the heroic myths were domestic records. He had a personal link with the memories which everywhere were most cherished by Dorians, no less than with those which appealed to men of "Cadmean" or of Achaean stock. And the wide ramifications of the Aegidae throughout Hellas rendered it peculiarly fitting that a member of that illustrious clan should celebrate the glories of many cities in verse which was truly Panhellenic.

Pindar is said to have received lessons in flute-playing from one Scopelinus at Thebes, and afterwards to have studied at Athens under the musicians Apollodorus (or Agathocles) and Labus of Hermione. In his youth, as the story went, he was defeated in a poetical contest by the Theban Corinna—who, in reference to his profuse employment of Theban mythology, is said to have advised him "to sow with the hand, not with the sack." There is an extant fragment in which Corinna reproves another Theban poetess, Myrtis, "for that she, a woman, contended with Pindar" (Ὀτάρης γυναῖκα Πινδήκα τινὸς ἔρωτας) —a sentiment which hardly fits the story of Corinna's own victory. The facts that stand out from these meagre traditions are that Pindar was precocious and laborious. Preparatory labour of a somewhat severe and complex kind was, indeed, indispensable for the Greek lyric poet of that age. Lyric composition demanded studies not only in metre but in music, and in the adaptation of both to the intricate movements of the choral dance (ὀρχηστής). Several passages in Pindar's extant odes glance at the long technical development of Greek lyric poetry before his time, and at the various elements of art which the lyrist was required to temper into a harmonious whole (see, e.g. Ol. iii. 8, vi. 91, xii. 48, xiv. 153; Pyth. xii. 23, &c.). The earliest ode so far authenticated (Pyth. v. 522) belongs to the twenty-first year of Pindar's age (502 B.C.); the latest (Olymp. v.) to the seventieth (452 B.C.). He visited the court of Hiero at Syracuse; Theron, the despot of Arcagras, also entertained him; and his travels perhaps included Cyrene. Tradition notices the special closeness of his relations with Delphi: "He was greatly honoured by all the Greeks, because he was so beloved of Apollo that he even received a share of the offerings; and at the sacrifices the priest would cry aloud that Pindar come in to the feast of the god." His wife's name was Megaceia (another account says Timoxena, but this may have been a second wife), and he had a son named Daiphantus and two daughters, Eumetis and Protopomachia. He is said to have died at Argos, at the age of seventy-nine, in 443 B.C.

Among the Greeks of his own and later times Pindar was pre-eminently distinguished for his piety towards the gods. He tells us that, "near to the vestibule" of his house (Pyth. iii. 78), choruses of maidens used to dance and sing by night in praise of the Mother of the Gods (Cybele) and Pan—deities peculiarly associated with the Phrygian music of the flute, in which other members of Pindar's family besides the poet himself are said to have excelled. A statue and shrine of Cybele, which he dedicated at Thebes, were the work of the Theban artists, Aristomedes and Socrates. He also dedicated a statue to Helius at Aegae, and another, by Calams, to Zeus. The latter god claimed his special veneration because Cyrene, one of the homes of his Aegid ancestry, stood "where Zeus Ammon hath his seat," i.e. near the oasis and temple

1 The references are to the edition of Pindar by C. A. M. Fennell (1893-1899), and the fourth edition of Bergk's Poetae lyrici greci.
PINDAR

(Pyth. iv. 16). The author of one of the Greek lives of Pindar says that, "when Pausanias the king of the Lacedaemonians was burning Thebes, some one wrote on Pindar's house, 'Burn not the house of Pindar the poet'; and thus it alone escaped destruction." This incident, of which the occasion is not further defined, has been regarded as a later invention.1 Better attested, at least, is the similar credence of Alexander the Great, when he sacked Thebes one hundred and eight years after the traditional date of Pindar's death (335 B.C.). He spared only (1) the Cadmeia, or citadel, of Thebes (thenceforth to be occupied by a Macedonian garrison); (2) the temples and holy places; and (3) Pindar's house. While the inhabitants were sold into slavery, exception was made only of (1) priests and priestesses; (2) persons who had been connected by private ἱερα with Philip or Alexander, or by public ἱερα with the Macedonians; (3) Pindar's descendants. It is probable enough, as Dio Chrysostom suggests (ii. 33), that Alexander was partly moved by personal gratitude to a poet who had celebrated his ancestor Alexander I. of Macedon. But he must have been also, or chiefly, influenced by the sanctity which in the eyes of all Hellenes surrounded Pindar's memory, not only as that of a great national poet, but also as that of a man who had stood in a specially close relation to the gods, and, above all, to the Delphian Apollo.2 Upwards of six hundred years after Pindar's death the traveller Pausanias saw an iron chair to which was attached among the oldest treasures of the temple in the sanctuary at Delphi. It was the chair, he was told, "in which Pindar used to sit, whenever he came to Delphi, and to chant those of his songs which pertain to Apollo" (x. 24, 5).

During the second half of Pindar's life, Athens was rising to that supremacy in literature and art which was to prove more lasting than her political primacy. Pindar did not live to see the Parthenon, or to witness the mature triumphs of Sophocles; but he knew the sculpture of Calamis, and he may have known the masterpieces of Aeschylus. It is interesting to note the feeling of that Athenian poet, who stands midway between the Homeric epics and Athenian drama, towards the Athenians of which Thebes was so often the bitterest foe, but with which he himself had so large a measure of spiritual kinship. A few words remain from a dithyramb in which he paid a glowing tribute to those "sons of Athens" who "laid the shining foundations of freedom" (ταῖς Ἀθηναίων ἐξελάχων φασάν κρατεῖν ἐλευθερίας, fr. 55, Bergk1, 77), while Athens itself is thus invoked: οἱ λατρείᾳ καὶ ὁσίτιον καὶ δωμαίῳ, Ἐλλάδος ἱερεία, κληριαὴ Ἀθήνα, δωμάτων πολιτείᾳ (fr. 54, Bergk1, 76). Isocrates, writing in 353 B.C., states that the phrase "Ἐλλάδος ἱερεία, the stay of Hellas," so greatly gratified the Athenians that they compared him with the "highest distinction of προβάτα (i.e. the highest appointed him honorary counsel, as it were—for Athens at Thebes), besides presenting him with a large sum of money (Anastasis, 166). One of the letters of the pseudo-Aeschines (Ep. iv.) gives an improbable turn to the story by saying that the Thebans had fined Pindar for his praise of Athens, and that the Athenians repaid him twice the sum.3 The notice preserved by Isocrates—less than one hundred years after Pindar's death—is good warrant for the belief that Pindar had received some exceptional honours from Athens. Pausanias saw a statue of Pindar at Athens, near the temple of Ares (i. 8, 4). Besides the fragment just mentioned, several passages in Pindar's extant odes bespeak his love for Athens. Its name is almost always joined by him with some epithet of praise or reverence. In alluding to the great battles of the Persian wars, while he gives the story of Plataea to the Spartans, he assigns that of Salamis to the Athenians (Pyth. i. 76). In celebrating (Pyth. vii.) the Pythian 1 A. Schäfer, Demosthenes und seine Zeit, iii. 119. 2 It will be remarked that history requires us to modify the statement in Milton's familiar lines: "The great Emathian conqueror bade spare The house of Pindarus, when temple and tower Went to the ground." Indeed, the point of the incident depends much on the fact that the temples and Pindar's house were classed together for exemption. 3 Compare Jephb, Attic Orators, ii. 143.

victory of the Athenian Megacles, he begins thus: "Fairest of preludes is the renown of Athens for the mighty race of the Alcmoneidae. What home, or what house, could I call mine by a name that should sound more glorious for Hellas to hear?" Referring to the fact that an Aeginetan victor in the games had been trained by an Athenian, he says (Nem. v. 49) "meet it is that a shaper of athletes should come from Athens"—and recollecting how often Pindar compares the poet's efforts to the athlete's, we may well believe that he was thinking of his own competition at Athens.

Pindar's versatility as a lyric poet is one of the characteristics remarked by Horace (Odys. iv. 2), and is proved by the fragments, though the poems which have come down entire represent only one class of compositions—the Εἰπικία, or odes of victory, commemorating successes in the great games. The lyric types to which the fragments belong, though it cannot be assumed that the list is complete, are at least numerous and varied.

(1) Τριπολι, Ημίγιον to deities—as to Zeus Ammon, to Persephone, to Fortune. The fragmentary ἱπποτρις entitled Ολυμπία (trans. of Pindar's Hymn to Zeus in the Olympic games) has been conjectured to celebrate the deities of Zeus, yet no evidence can be pointed to of the construction of a protecting god, especially Apollo, Artemis or Zeus. (2) Πολεμικοὶ Προμήχευς, sung by choruses in honour of Dionysus (cf. Pind. Ol. xiii. 18, τα δυνατὸν τὸν ἐξωτικὸν σὺν βοήθησαν Χάρτης τὰ χάριτα ὁμώνυμη—where Pindar alludes to the choral form given to the dithyramb, sung by Artemes, after the festival of the Dionysiac Games, "winning an ox as prize."). (3) Πολίκα, Πολικικοὶ, Processional Songs, choral chants for worshippers approaching a shrine. One was written by Pindar for the Delians, another for the Aeginetans. (4) Κορομοί, Choral Songs. The reference in Pyth. iii. 78 to maidsens worshiping Cybele and Pan near the poet's house is illustrated by the fact that one of these Panikeia invoked Pan, lord of Arcadia, attendant of the Great Mother, watcher of the great Panis, thus being, possibly, a kind of Choral Dance-Songs, adapted to a lively movement, used from an early date in the cult of Apollo, and afterwards in that of other gods, while the use of the word Πολίκα is finally associated with Dionysus. In the Pythian and Isthmian Games, forty-five, of the finest fragments (84, Bergk1, 107), written for the Thesbiacs in competition with the propitiatory rites after an eclipse of the sun, probably that of the 50th of April 453 B.C. (7) Εὐαλία, Σongs of Praise (for men, while ñuors were for gods), to be sung by a σῶμα or festal company. In strictness ἐυαλία was the genus of which ἐνθύμων was a species; but the latter is more conveniently treated as a distinct kind. Pindar wrote encomia for Theron, despot of Acrasus, and 'for the grand father of Pericles. A number of small fragments, which cannot be classified, are usually given as ἐκ ἄλλων ἀλλότριων, 'of uncertain class.' On comparing the above list with Horace, Odes, iv. 2, it will be seen that he alludes to No. 3 (dithyramb); Nos. 1 and 2 (ιπποτρις), to the old Olympic victory of M. A. S. G. (flebō sponsae jenomenae raptum Florum); as well as to the extant Πολικία (see igio Euse domum reduxit Palma cedast). The Εἰπικία.—The Πολικία (sc. μῆλον), or Πολικία (sc. ὑμοίον, "Odes of Victory," form a collection of forty-four odes, traditionally divided into four books, answering to the four great festivals: (1) Ολυμπιακά (sc. θυρίαν): fourteen odes for winners of the wild olive-branch in the Olympic games, held at Olympia in honour of Zeus once in four years; (2) Πολικά: twelve odes for winners of the laurel-branch in the Pythian games, held at Delphi in honour of Apollo, once in four years, the third of which was given to the winner of the pine-branch in the Nemean games, held at Nemea, in honour of Zeus, once in two years, the second and fourth of each Olympiad; and (4) Ισθμικά: seven odes for winners of the parsley branch in the Isthmian games, held at the Isthmus
of Corinth, in honour of Poseidon, once in two years, the first and third of each Olympiad. The Greek way of citing an ode is by its place, followed by the numeral, e.g. "the ninth Olympian" is "Οἰκετέωνος ζής". The chronological range of the collection (so far as ascertainable) is from 502 B.C. (Pyth. x.) to 452 B.C. (Ol. v.). With respect to the native places of the victors, the geographical distribution is as follows: for the mainland of Greece proper, 13 odes; for Aegina, 11; for Sicily, 15; for the Epizephyrian Locrians (southern Italy), 2; for Cyrene (Africa), 3.

The general characteristics of the odes may be briefly considered under the following heads: (1) language; (2) treatment of theme; (3) sentiment—religious, moral and political; (4) relation to contemporary events. 2. The manner of Pindar is distinct in character from that of every other Greek poet, being almost everywhere marked by the most imaginative boldness. Thus (a) metaphor is used even for the expression of common ideas, or the translation of familiar phrases, as when a cloak is called (Ol. ix. 97) "a warm remedy for winds." (b) Images for the highest excellence are drawn from the farthest limits of travel or navigation, or from the fairest of natural objects; as when the superlative hospitality of a man who kept open house all the year round is described by saying, "far as to Phasis was his voyage in summer days, and in winter to the shores of Nile" (Isthm. ii. 41); or when Olympia, the "crown" or "flower" of festivals, is some absolute excellence, water, bright as gold, brilliant as the noonday sun (Ol. i. ad init.). This trait might be called the Pindaric imagery of the superlative. (c) Poetical inversion of ordinary phrase is frequent; as, instead of, "he struck fear into the beasts," "he gave the beasts to fear" (Pyth. v. 50). (d) The efforts of the poet’s genius are represented under an extraordinary number of similitudes, borrowed from javelin-throwing, chariot-driving, leaping, rowing, sailing, ploughing, building, shooting with the bow, sharpening a knife on a whetstone, mixing wine in a bowl, and many more. (e) Homely images, from common life, are not rare; as from account-keeping, usury, sending merchandise over sea, the stern or secret dispatch, &c. And we have such homely proverbs as, "he hath his foot in this shoe." 3. The standard of Pindar’s odes rests on a constant recognition of the limits imposed by the divine will on human effort, combined with strenuous exertion that each man should strive to reach the limit allowed in his own case. Native temperament (φυσις) is the grand source of all human excellence (αὐτοτης), while such excellences as can be acquired by study (κατὰ αναλογίαν, Ol. ix. 100) are of relatively small value—The sentiment, we may remark, of one whose thoughts were habitually conversant with the native qualities of a poet on the one hand and of an athlete on the other. The elements of ὁρίζεται δῆδος—"sane happiness," such as has least reason to dread the jealousy of the gods—are substance sufficient for daily wants and good repute (εὐδοκία). He who has these should not "seek to be a god." (f) Wealth set with virtues (πλοῦτος ἀρετής διδύμῳμενος), as gold with precious gems, is the most fortunate lot, because it affords the amplest opportunities for honourable activity. Pindar does not rise above the ethical standard of an age which said, "love thy friend and hate thy foe" (cf. Pyth. ii. 83; Isthm. iii. 65). But in one sense he has a moral elevation which is distinctively his own; he is the glowing prophet of generous emulation and of reverent self-control.

c. The political sentiments of the Theban poet are suggested by Pyth. xi. 52; "In politics I find the middle state crowned with more enduring good; therefore praise I not the despots’ portion; those virtues move my zeal which serve the folk." If in Pyth. ii. 87, a democracy is described as ὁ λαός σφραγις, "the raging crowd," it is to be noted that the ode is for Hiero of Syracuse, and that the phrase clearly refers to the loyalty of those of the other political party. The advances made by the Dorian race, and of those in the city; in the 5th century B.C., more than once convulsed Sicilian cities. At Thebes, after the Persian wars, a "constitutional oligarchy" (κακοφαβίς ισθιομός, Thuc. iii. 62) had replaced the narrower and less temperate oligarchy of former days (ναυαρχεία ὀ πέτω νόμων); and in this we may probably recognize the phase of Greek political life most congenial to Pindar. He speaks of a king’s lot as unique in its opportunities (Ol. i. 113); he sketches the character of an ideal king (Pyth. iii. 71); but nothing in his poetry implies liking for the τυραννίς as a form of government. Towards the Greek princes of Sicily and Cyrene his tone is ever one of manly independence; he speaks as a Greek citizen whose lineage places him on a level with the proudest of the Dorian race, and whose offices invest him with an almost sacred dignity. In regard to the politics of Hellas at large, Pindar makes us feel the new sense of leisure for quiet pursuits and civilizing arts which came after the Persian wars. He honours "Quarantilla, the friend of cities" (Ἄπτυχος φιλόπόλιος, Ol. iv. 10). The epic poet sang of wars; Pindar celebrates the "rivalries of peace."

4. Pindar’s genius was boldly original; at the same time he was an exquisite artist. "Mine be it to invent new strains, mine the skill to hold my course in the chariot of the Muses; and may courage go with me, and power of ample grasp" (Ol.)
PINDARICS

ix. 86). Here we see the exulting sense of inborn strength; in many other places we perceive the feeling of conscious art—as in the phrase ἐνάλημα, so apt for his method of infusing an ode with mythical subjects, or when he compares the opening of a song to the front of a stately building (Ol. vi. 33) or the symphony with the gestures of nature was deeper and keener than is often discernible in the poetry of his age. It appears, for example, in his welcome of the season when "the chamber of the hours is opened, and delicate plants perceive the fragrant spring" (fr. 53, Bergk. 73); in the passage where Jason invokes "the rushing strength of waves and winds, and the nights, and the paths of the deep" (Pyth. iv. 195); in the lines on the eclipse of the sun (fr. 84, Bergk. 107); and in the picture of the eruption, when Etna, pillar of the sky, nurse of keen snow all the year," sends forth "pure springs of fire unapproachable" (Pyth. i. 29). The poet's feeling for colour is often noticeable—as in the beautiful story of the birth of Iamus—when Evadne lays aside her silver pitcher and her girdle of scarlet web; the babe is found, "its delicate body steeped in the golden and deep purple rays of pansies" (Ol. vi. 53).

The spirit of art, in every form, is represented by Pindar by χάρας—"the source of all delights to mortals" (Ol. i. 30)—or by the personified Charites (Graces). The Charites were often represented as young maidens, decking themselves with early flowers—the rose, in particular, being sacred to them as well as to Aphrodite. In Pindar's mind, as in the old Greek conception from which the worship of the Charites sprang, the instinct of beautiful art was inseparable from the sense of natural beauty. The period from 500 to 600 B.C. to which most of Pindar's extant odes belong, marked a stage in the development of Greek sculpture. The schools of Argos, Sicyon and Aegina were effecting a transition from archaic types to the art which was afterwards matured in the age of Phidias. Olympia forms the central link between Pindar's poetry and Greek sculpture. From about 565 B.C. onwards sculpture had been applied to the commemoration of athletes, Chiefly at Olympia. In a striking passage (Nem. v. ad. init.) Pindar recognizes sculpture and poetry as sister arts employed in the commemoration of the athlete, and contrasts the merely local effect of the statue with the wide diffusion of the poem. "No sculptor I, to fashion images that shall stand idly on one pedestal for aye; no, go thou forth from Aegina, sweet song of mine, on every freighted ship, on each light bark." Many particular subjects were common to Pindar and contemporaneous sculpture. Thus (1) the sculptures on the east pediment of the temple at Aegina represented Heracles coming to seek the aid of Telamon against Troy—a theme brilliantly treated by Pindar in the fifth Isthmian; (2) Heracles' victory in the chariot-race was commemorated at Olympia by the joint work of the sculptors Onatas and Calamis; (3) the Gigantomachia, (4) the wedding of Heracles and Hebe, (5) the wars of the Centaurs with the Lapithae, and (6) a contest between Heracles and Apeolus are instances of mythical material treated alike by the poet and by sculptors of his day. The contemporary improvements in town architecture, introducing spacious and well-paved streets, such as the συνάντησις at Cyrene (Pyth. v. 87), suggests his frequent comparison of the paths of song to broad and stately causeways (πορεία πρώσοδος—στρατηγοῦ κλείνω, Nem. vi. 47; Isthm. vi. 22). A song is likened to cunning work which yields gold, ivory and coral (Nem. vii. 79). Pindar's feeling that poetry, though essentially a divine gift, has a technical side (σωφρα), and that on this side it has had an historical development like that of other arts, is forcibly illustrated by his references to Ionian artists, women (cf. frs. 75 ἐν ἅλλης δ��οις, and 86 ἐν ἅλλης δ��οις, which Corinth had early been famous. He instances (1) the development of the dithyramb, (2) certain improvements in the harnessing and driving of horses, and (3) the addition of the pediment to temples (Ol. xiii. 21).

In the development of Greek lyric poetry two periods are broadly distinguished. During the first, from about 600 to 500 B.C., lyric poetry is local or tribal—as Alcaeus and Sappho write for Lesbians, Alcmene and Stesichorus for Doriens. During the second period, which takes its rise in the sense of Hellenic unity created by the Persian wars, the lyric poet addresses all Greece. Pindar and Simonides are the great representatives of this second period, to which Bachylices, the nephew of Pindar, also belongs. They are also the last of the lyric poets to be classed by German writers as die universellen Meliker. The Greeks usually spoke, not of "lyric," but of "melic" poetry (i.e. meant to be sung, and not, like the epic, recited); and "universal melic" is lyric poetry addressed to all Greece. But Pindar is more than the chief extant lyricist. Epic, lyric and dramatic poetry succeeded each other in Greek literature by a natural development. Each of them was the spontaneous utterance of the age which brought it forth. In Pindar we can see that phase of the Greek mind which produced Homeric epics passing over into the phase which produced Athenian drama. His spirit is often thoroughly dramatic—witness such scenes as the interview between Jason and Pelias (Pyth. iv.), the meeting of Apollo and Chiron (Pyth. i.), the episode of Castor and Polydeuces (Nem. x.), the entertainment of Heracles by Telamon (Isthm. v.). Epic narrative alone was no longer enough for the men who had known that great trilogy of national life, the Persian invasions; they longed to see the heroes moving and to hear them speaking. The poet of Olympia, accustomed to see beautiful forms in vivid action or vivid art, was well fitted to be the lyric interpreter of the new dramatic impulse. Pindar has more of the Homeric spirit than any Greek lyric poet known to us. On the other side, he has a genuine, if less evident, kinship with Aeschylus and Sophocles. Pindar's work, like his art itself, illustrates the spiritual unity of Greek art.

The fact that certain glosses and lacunae are common to all our MSS. of Pindar makes it probable that these MSS. are derived from a common archetype. Now the older scholia on Pindar, which appear to have been compiled mainly from the commentaries of Didymus (c. 15 B.C.), sometimes presuppose a purer text than the one now extant. But the conjectures of the later MSS. (A.D. 160). The archetype of our MSS., then, cannot have been older than the end of the 2nd century. Our MSS. fall into two general classes: (1) an early group, representing a text which, though often corrupt, is comparatively free from later interferences; and (2) the later, which exhibit the traces of a Byzantine recension, in other words, of less critical, down to the 14th or 15th century. To the first class belong Parisius 7, breaking off in Pyth. v. Ambrosianus 1, which has only Ol. i.—xii.; Medicus 2; and Vaticanus 2—the two last-named of the highest value. The edition philicus is the Aldine (Venice, 1513). A modern study of the text of Pindar has been made by Professor T. W. Harman (1880), and a large part has been translated (1917) by W. V. Harris. A modern edition (1773). Hermann did much to advance Pindaric criticism. But August Böckh (1811—1821), who was assisted in his commentary by L. Dissen, is justly regarded as the founder of a scientific treatise on the poet. The edition of the Iliad of 1824, by F. C. Tiedemann, graci, new ed. by O. Schröder (1900) is marked by considerable boldness of conjecture, as that of Tycho Mommsen (1864) by a sometimes excessive adherence to MSS. A recession by W. Christ has also been published in Teuber's series (2nd ed., 1896), also with Prolegomena and commentary (1896); and by O. Schröder (1908). The complete edition of W. J. Donaldson (1841) has many merits; but that of C. A. F. Fernell (1879—1883; new ed., 1889—1889) is better adapted to the needs of English students. The Olymphia and Pythia have been edited by B. L. Gildersleeve (1885); the Nemesis and Isthmia by W. Bury (1890—1902); the Scholia by I. A. Abel (1890, unfinished), and A. B. Graber (1903). There is a special lexic by J. Rumpel (1890). The translation into English prose by Ernest Myers (2nd ed., 1883) is excellent; verse translation by T. C. Baring (1875), and of the Olympian Odes by William Metcalfe (1916) is excellent; last, but not least, J. H. J. Schmidt, in Die Kunstformen der griechischen Poesie (Leipzig, 1868—1872). On Pindar generally, see monographs by A. V. Villeneuv (1839), L. Schmidt (1862), G. Lübbei (1888), J. C. Christ (1890), and A. B. Graber (1903). There is a special reference to chronological questions and Pythia, i., ii., iii. Some considerable fragments of the poems were discovered in 1906 by B. D. Morice in Blackwood's Ancient Classics for English Readers. Exhaustive bibliographical information on the earlier literature will be found in Engelmann, Scriptores Graeci antiquissimi; see also van der Horst (1899), and Cd. W. B. Carver, Cxvi. 1904, with special reference to chronological questions and Pythia, i., ii., iii. Some considerable fragments of the poems were discovered in 1896 by B. D. Morice and A. S. Hunt (see Oxyrhyncus papyri, pt. ii. pp. 24—81); some critical notes will be found in Classical Review, Feb. 1908 (A. E. Housman). (R. C. J. X.)

PINDARICS, the name by which was known a class of loose and irregular odes greatly in fashion in England during the close
of the 17th and the beginning of the 18th century. The invention is due to Abraham Cowley, who, probably in Paris—"a place where he had no other books to direct him"—and perhaps in 1659, found a text of Pindar and determined to imitate the Greek poetry in English, without having comprehended the system upon which Pindar's prosody was built up. Cowley published, however, in 1656, 'fifteen Pindarique Odes,' which became the model on which countless imitators founded their pindarics. The erroneous form of these poems, which were absolutely without discipline of structure, was first exposed by Congreve, exactly half a century later, he very justly describing them as "bundles of rambling incoherent thoughts, expressed in a like parcel of irregular stanzas, which also consist of such another complication of disproportionate, uncertain and perplexed verses and rhymes." This is harsh, but it describes a pindaric with absolute justice. Cowley had not been aware that "there is nothing more regular than the Odes of Pindar," and that his poems were constructed in harmony with rigid prosodical laws in strophe, antistrophe and epode; "the liberty which Pindar took in his numbers, which has been so much misunderstood and misapplied by his pretended imitators, was only in varying the stanzas in different odes; but in each particular, was correspondent to another stanza of the same turn, and according to the order of the ode." These excellent critical remarks were made by Congreve in his Discourse on the Pindarique Ode of 1706, and from that date forward the use of pindarics ceased to be so lax and frantic as it had been during the previous fifty years. The time had now passed in which such a critic as Sprat could praise "this loose and unconfined measure" as having "all the grace and harmony of the most confined." It began to be felt that the English pindaric was a blunder founded upon a misconception. If we examine Cowley's "Resurrection," which was considered in the 17th century to be a model of the style, and "truly pindarical," we find it to be a shapeless poem of 64 lines, arbitrarily divided, not into strophes, but into a series of stanzas, according to another stanza of the same turn, and according to the order of the ode. These excellent critical remarks were made by Congreve in his Discourse on the Pindarique Ode of 1706, and from that date forward the use of pindarics ceased to be so lax and frantic as it had been during the previous fifty years. The time had now passed in which such a critic as Sprat could praise "this loose and unconfined measure" as having "all the grace and harmony of the most confined." It began to be felt that the English pindaric was a blunder founded upon a misconception. If we examine Cowley's "Resurrection," which was considered in the 17th century to be a model of the style, and "truly pindarical," we find it to be a shapeless poem of 64 lines, arbitrarily divided, not into strophes, but into a series of stanzas, according to another stanza of the same turn, and according to the order of the ode.

The very laxity of these pindarics attracted the poets of the unlyrical close of the 17th century, and they served the purpose not only of Dryden and Pope, but of a score of lesser poets, among whom Oldham, Mrs Behn, Otway, Sprat, Flatman and many others were prominent. The pindaric became the almost necessary form in which to indite a poem of compliment on a birth, a wedding or a funeral. Although the vogue of these forms hardly survived the age of Anne, something of the vicious tradition of them still remained, and even in the odes of Wordsworth, Coleridge and Southey, the broken versification of Cowley's pindarics occasionally survives. Tennyson's Ode on the Death of the Duke of Wellington (1852) is the latest important specimen of a pindaric in English literature. (E. G.)

PINDARIS, a word of uncertain origin, applied to the irregular horsemen who accompanied the Mahratta armies in India during the 18th century when the Mughal Empire was breaking up; loosely organized under self-chosen leaders, each band was usually attached to one or other of the great Mahratta chieftains. Their special characteristic was that they received no pay, but rather purchased the privilege of plundering on their own account. The majority of them seem to have been Mahomedans: when the regular forces of the Mahrattas had been broken up in the campaigns conducted by Sir Arthur Wellesley and Lord Lake in 1802–04, the Pindaris made their headquarters in Malwa, under the tactful protection of Sindia and Holkar. They were accustomed to assemble every year at the beginning of November, and sail forth into British territory in search of plunder. In one such raid upon the Masulipatam coast they plundered 339 villages, killing or wounding 682 persons, torturing 3600 and carrying off property worth a quarter of a million. In 1808–09 they plundered Gujarat, and in 1812 Mirzapur. In 1814 they were reckoned at 25,000 to 30,000 horsemen, half of them well armed. At last the evil became intolerable, and in the 1817 the marquess of Hastings obtained the consent of the East India Company to the organized campaign, known as the Pindari War. The Pindaris were surrounded on all sides by a great army, consisting of 120,000 men and 300 guns, which converged upon them from Bengal, the Deccan and Gujarat under the supreme command of Lord Hastings in person. Sindia was overawed and forced to sign the treaty of Gwalior, consenting to aid in the extirpation of the Pindaris, whom he had hitherto protected. The Peshwa at Poona, the Bhonsla raj at Nagpur and the army of the infant Holkar each took up arms, but were separately defeated. The Pindaris themselves offered little opposition. Amur Khan, by far their most powerful leader, accepted the conditions offered to him; and his descendant is now Nawab of the state of Tonk in Rajputana. The rest surrendered or were hunted down, the fate of Chitu, one of the most notorious, being to perish in a tiger's den. These military operations were followed by the pacification of Central India under the administration of Sir John Malcolm.

See J. Grant Duff, History of the Mahrattas (1826); and Major Ross of Bludensburg, Marquees of Hastings (Rulers of India Series) (1913).

PINDADAN KHAH, a town of British India, in the Jhelum district of the Punjab, situated near the right bank of the river Jhelum, on the Sind-Sagar branch of the North-Western railway. Pop. (1901), 13,770. It is an important centre of trade, and its manufactures include boats, brass-ware, pottery, embroidered scarves and riding-whips.

PINDUS, the ancient name of the rugged group of mountains which separates Thessaly from Epirus, and branches south in various directions. The geographical name is sometimes extended over all these branches, and so reaches from Aetolia to the Gulf of Lamia. The northern part of the ridge was known as Lacon. There is no modern name covering the whole range, but its different parts have separate names. Several of these range to a height of 7000 ft. or more.

PINE (Lat. Pinus, Gr. πῖνος), a name given by the ancients to some of the resinous cone-bearing trees to which it is now applied, and, as limited by modern botanists, the designation of a large genus of true conifers, differing from the firs in their hard woody cone-scales being thickened at the apex, and in their slender needle-shaped leaves growing from a membranous sheath, either in pairs or from three to five together—each tuft representing an abortive branch, springing from the axil of a partially deciduous scale-leaf, the base of which remains closely adherent to the stem. The numerous male catkins are generally arranged in dense whorls around the bases of the young shoots; the anther-scales, surmounted by a crest-like appendage, shed their abundant pollen by longitudinal slits; the two ovules at the base of the inner side of each fertile cone-scale develop into a pair of winged seeds, which drop from the opening scales when mature—as in the allied genera.

The pines are widely distributed over the north temperate zone, in the southern portions chiefly confined to the mountains, along which, in Central America, a few are found within the tropic; in more northern regions they frequently form extensive forests, sometimes hardly mingled with other trees. Their soft, straight-grained, resinous and often durable wood gives to many kinds a high economic value, and some are among the most esteemed of timber trees.

Of the two-leaved species, P. sylvestris, the pine of northern Europe, may be taken as a type. When growing in perfection it is one of the finest of the group, and perhaps the most picturesque of all forest trees; attaining a height of from 70 to 120 ft., it is of conical growth when young, but in maturity acquires a spreading cedar or mushroom-like top, with a straight trunk of from 2 to 4 ft. in diameter at the base, and gnarled twisted boughs, densely clothed at the extremities with glaucous green foliage, which contrasts strongly with the fiery red-brown bark. The leaves are rather short, curved, and often twisted; the male catkins, in dense cylindrical whorls, fill the air of the forest with their sulphur-like pollen in May or June, and fecundate the purple female flowers, which, at first sessile and erect, then
become recurved on a lengthening stalk; the ovate cones, about the length of the leaves, do not reach maturity until the autumn of the following year, and the seeds are seldom scattered until the third spring; the cone-scales terminate in a pyramidal

recurved point, well marked in the green state and in some varieties in the mature cone, but in others scarcely projecting. *P. sylvestris* is found, in greater or less abundance, from the hills of Finmark and the plains of Bothnia to the mountains of Spain and even the higher forest-slopes of Etna, while in longitude its range extends from the shores of the North Sea to Kamchatka. Nowhere more abundant than in the Scandinavian peninsula, this tree is the true fir (*fur, fura*) of the old Norsemen, and still retains the name among their descendants in Britain, though botanically now classed as a pine. It grows vigorously in Lapland on the lower ground, and is found even at an elevation of 700 ft., while in south Norway it occurs up to 3000 ft., though the great forests from which "Norway pine" timber is chiefly derived are on the comparatively lower slopes of the southeastern dales; in the highest situations it dwindles to a mere bush. It furnishes the yellow deal of the Baltic and Norway. In Germany, both on the mountains and the sandy plains, woods of "kiefer" are frequent and widely spread, while vast forests in Russia and Poland are chiefly composed of this species; in many northern habitats it is associated with the spruce and birch. In Asia it abounds in Siberia and on the mountains of the Amur region; on the European Alps it occurs at a height of 3600 ft., and on the Pyrenees it is found at still higher elevations; on the northern side of Etna it is said to grow at above 7000 ft. In Britain natural forests of Scotch fir of any extent are only now found in the Highlands, chiefly on the declivities of the Grampians. In former ages the tree covered a large portion of the more northern part of the island, as well as of Ireland; the numerous trunks found everywhere in the mosses and peat-bogs

of the northern counties of England attest its abundance there in prehistoric times; and in the remoter post-Glacial epoch its range was probably vastly more extended. The tree is not at present indigenous in southern Britain, but when planted in suitable ground multiplies rapidly by the wind-sown seeds; on many of the sandy moors and commons natural pine woods of large extent have been thus formed during the last fifty years. The Scotch fir is a very variable tree, and certain varieties have acquired a higher reputation for the qualities of their timber than others; among those most prized by foresters is the one called the Braemar pine, the remaining fragments of the great wood in the Braemar district being chiefly composed of this kind; it is mainly distinguished by its shorter and more glaucous leaves and ovoid cones with blunt recurved spines, and especially by the early horizontal growth of its ultimately drooping boughs; of all varieties this is the most picturesque. On the European continent the Hagenau pine of Westphalia is esteemed for the straightness and good quality of its timber. The heart-wood of the finer kinds of Scotch fir is of a deep brownish-red colour, abounding in the resin to which its durability is probably due. For all indoor and most outdoor purposes it is as lasting as oak, and for ship planking is perhaps little inferior; from its lightness and elasticity it is well adapted for the construction of yachts and other small fast-sailing craft, and is said to be the best of all wood for masts and large spars; its weight varies from 30 to 40 lb the cubic foot. The sap-wood is more perishable, but it is useful for fences, casks and a variety of other purposes; soaking in lime-water renders it more lasting; great numbers of young pines are annually cut for railway sleepers, mining timber and numerous agricultural applications; large quantities are consumed for wood-pavement. The quality of the timber

flourishes, and it is always indifferent; it is usually said that the wood is best in the cold climate of its more northern habitats, but a trunk (4 ft. in diameter) grown on the sands of Surrey had heart-wood quite equal to any produced in Glenmore or Rothiemurchus. The rapidity of growth is still more variable: in Britain full maturity is attained in from seventy to one hundred and twenty years, but in Norway the trunk increases much more rapidly. Schübel observes that a tree felled in the Alten district (about 70° lat.), measuring 2 ft. 10 in. in diameter without the bark, showed four hundred circles of annual growth.

In Norway the tree, growing in dense forests, is generally of but moderate girth, and probably this pine nowhere reaches a greater size than in the Scottish woods; a plank from Glenmore forest measured nearly 2 ft. across, and from 3 to 4 ft. is not an unusual diameter for a British pine tree.

Vast numbers of Scotch firs are raised in nurseries for artificial planting; the seed is sown in the spring, being just covered with earth, and the seedlings transplanted in the second year into rows for further culture, or taken direct from the seed-bed for final planting; sometimes the seed is sown where the trees are intended to grow. A plantation of Scotch fir requires frequent and careful thinning as the young trees increase in size; but pruning should be avoided as much as possible, excepting for the removal of dead wood. Plantations in England are generally ready for final cutting in from sixty to seventy years, and many are cleared at a much earlier stage of growth. *P. sylvestris* in Britain is liable to many insect depredations: the pine-chafer, *Hylurgus pini-persa*, is destructive in some places, the larva of this beetle feeding on the young succulent shoots, especially in young plantations; *Hylotis abietis*, the fir-weevil, eats away the bark, and numerous lepidopterous larvae devour the leaves; the pine-roller is also injurious in some seasons; the removal of all dead branches from the trees and from the ground beneath them is recommended, as most of these insects lay their eggs among the decaying bark and dead leaves. In common with other pines, *P. sylvestris* is subject to the attacks of various fungi. *Trameles radiciperda* attacks the roots and penetrates to the stem, causing rotting of the wood; the disease is difficult to eradicate, as the mycelium of the fungus travels from root to root in the soil. Rotting of the wood at the base of the trunk is also caused by *Agaricus melius*, which spreads from root to root in the soil by means of its long purple-black, cord-like mycelium. A known as *Rhiematophyllum* has also been caused by species of *Peridermium*, which often invade the cortex and cambium to such an extent as to "ring" the stem or branch, or to cause an abnormal formation of turpentine which soaks into the wood and stops the upward passage of water; this causes the parts above the diseased area to perish. In England the pine is largely employed as a "nurse" for oak trees, its conical growth when young admirably adapting it for this purpose; its dense foliage renders it valuable as a shelter tree for protecting land from the wind; it stands the sea gales better than most conifers, but will not flourish on the shore like some other species.

The pine is an important tree in the economy of the northern nations of Europe. In Scandinavia and Russia houses are chiefly constructed of its timber; and log-huts are made of the smaller trunks and lined and roofed with the bark. The inner bark is twisted into ropes, and, like that of the spruce, is kiln dried, ground up, and mixed with meal in times of scarcity; in Kamchatka it is macerated in water, then pounded, and made into a kind of substitute for bread without any admixture of flour. In recent days the fibre of the leaves has been extracted in some quantity and applied to textile purposes under the name of *walsvuller*, both in Germany and Sweden. It is prepared by boiling the needles in a solution of soda to remove the resin, which process loosens the fibre and renders its separation easy; it has some resemblance to coarse wool, and is spun and woven into blankets and garments that are said to be warm and durable; it is also used for stuffing cushions; an essential oil, obtained by a previous distillation of the leaves, has medicinal virtues attributed to it by some German practitioners.

Large quantities of turpentine are extracted from this pine in Sweden and Russia by removing a strip of bark, terminating below in a deep notch in the wood, into which the turpentine runs, and from which it is scooped as it accumulates; but the product is not equal to that of the silver fir and other species. Tar is prepared largely from *P. sylvestris*; it is chiefly obtained from the roots, which, mingled with a few logs, are arranged in a long line, from which, when dry, it is carefully removed by a flame or bank; after filling up, the whole is covered with turf and fired at the top, when the tar exudes slowly and runs into an iron vessel placed below, from the spout of which it is conveyed into barrels. Most of the so-called Stockholm tar is thus prepared, chiefly in the province of Bothnia.

Closely allied to the Scotch pine, and perhaps to be regarded as a mere alpine form of that species, is the dwarf *P. montana* (or *P. Pumilio*), the "knorrholm" or "kniole" of the Germans—a small spruce, not exceeding 6 ft. in height, with branches and stems, that root occasionally at the knee-like bends where they rest upon the ground. The foliage much resembles that of the Scotch fir, but is shorter, thinner and more rigid; the cones are smaller but similar in form. Abounding on the higher Bavarian and Tirolese Alps, it is a favourite shelter for the chamois; the hunters call it the "latschen," from its recurrent straggling growth. The cambium destroys turpentine formation in rhizomus and for brushes and spains, is distilled from the young branches, and a fragrant white resin that exudes in some quantity from the buds is used for similar purposes and as a medicine. In the alpine districts of the Austrian Tyrol and Bavarian Forest is the dwarf spruce, *P. australs*; a seasoning spruce of the smaller growth.

The red pine of Canada and New England (so called from the colour of its bark), *P. resinosa*, is a tree of considerable size, some- times over 100 ft. in height, and forming the usual coniferous forest; its glaucous leaves form dense tufts at the ends of the branches, and are 4 or 5 in. long; the ovate blunt cones are about half that length. The tree is of quick growth and the wood strong and durable, but it is less used than Scotch fir, though much employed in ship-building; according to Emerson, trunks exist in Maine 4 ft. in diameter. A sandy soil seems to suit it best, and the suitability of the ground for the purpose of growth. Red pines abound in Nova Scotia and Newfoundland, and the tree is rather widely distributed over the northern parts of the continent; it rarely forms extensive woods, but grows chiefly in small groups on sandy, or rather in sandy soils, though sometimes found in morasses. It is a pioneer tree in the virgin forest, and is still present in the greater part of the northern states of America, and is chiefly remarkable for its much recurved and twisted cones, about 2 in. long. The trunks are too small to be of great economic value, but the light wood is used by the natives for their canoes.

Like the Scotch pine, the western pine is one of the noblest trees of this group, growing to a height of 200 or 300 ft., with a straight trunk and branches in regular whorls, forming in large trees a pyramidal head; the slender leaves, of a dark green tint, are from 0.3 to 2.4 inches long; the cones range from 2 to 6 inches in length, are of the same size as the branches, and are deciduous; the cone scales are ovate, furnished with a tapering crest, of a light brown colour. This pine abounds in Corsica, and is found in more or less abundance in Spain, southern France, Greece, and many Mediterranean countries; it is a most valuable timber, and is extensively used in all Europe, for rapid growth, but produces good timber, much used in southern dockyards, and very durable, though less strong than that of *P. sylvestris*; the heart-wood is of a brownish-tint. In southern France it has been planted with success on the drift-sands of the Bay of Biscay, though it does not bear the full force of the sea-blast as well as the pinaster. In England it grows well in sheltered situations and well-drained soil. *Pinus pinea*, the Italian pine, *P. laricio*, was generally now regarded as a variety of *P. Laricio*, derives its name from the extreme depth of its foliage tints—the sharp, rigid, rather long leaves of a dark green hue giving it a thickly heaped appearance; the cones are usually 2 in. long, reddish-brown; the terminal cones are generally in pairs, but sometimes three or four together. The tree is conical when young, but when old forms a spreading head; it often attains a large size. Southern Europe is the abode of the adjutant species of this pine; it seems to flourish best on rocky mountain sides, but in England grows well on sandy soils. The timber is valued in its native country, and is said to be durable and to stand exposure to weather better than any other wood in Italy. The heart-wood is reddish brown, the bark being thick and brown. In *P. pumilio*, the cones are solitary, oblong, conical and of a yellow tint. The timber is used in Spanish dockyards, but opinions vary as to its quality. In plantations its bright foliage, with the orange cones and round shooks, renders it an ornamental tree, hardy in southern Britain. *P. brutia*, the Calabrian pine, is regarded as the same.
species. *P. halpensis*, another Mediterranean form, is valued for its timber, which, with a tall trunk and resinous wood, makes it useful for the crown. The cluster pine or pinaster, an important species from its vigorous growth in the sand-drifts of the coast, for the purpose of binding which it has been grown more extensively and successfully than any other tree, especially on the dunghills of the district of Biscay. Growing to a height of from 40 to 80 ft., the deeplyfurrowed trunk occasionally reaches a diameter of 3 ft. or more at the base, where, like most sand trees, it usually curves upward gradually with the sand, and becomes more and more curved as it is drawn out from the trunk; the ovate cones are from 4 to 6 in. long, of a light shining brown hue, with thick scales terminating in a pyramidal apex; they are arranged around the head of the tree almost horizontally, the lower leaves being in pairs, the pairs terminating in a sharp incurved prickle. The timber of this pine is indifferent, but the forests of it are of importance from the quantity of turpentine they yield; the trees also furnish excellent sleepers.

*P. ponderosa*, the yellow pine of the Pacific coast of America, belongs to this section; it is a fine timber tree deserving of notice from the extreme density of its wood, which barely floats in water; it abounds in some parts of the western range of the Rocky Mountains, and is the most widely distributed pine tree of the mountain forests of western North America. The leaves are long and twisted, the small oval cones armed with recurved prickles; the tree is said to be of rapid growth. In Oregon and California several large pines of this group are found. *P. Coulteri* or *macrocarpa*, is remarkable for its enormous cones (sometimes a foot long), the persistent scales of which have the same elongated, lamelliform, thick, imbricate edges as the scale-leaves of the prepared coniferous trees, in long hooked points curving upwards; the leaves are long, rigid, and glaucous in hue. Nearly related to this is *P. Sabiniiana*, the nut-pine of California, the cones of which are 7 to 9 in. long and curved, the plates of the scale-leaves recurved once or twice, the seeds are eaten by the Indians; the tree is one of the largest of the section, sometimes attaining a height of 120 ft. and upwards, while trunks have been found, it is said, 10 or 12 ft. in diameter. *P. Grapevallis*, or the Himalayan pines, is remarkable for the large growth of its lax slender leaves, of a grass-green tint; the cones have the points of the scales recurved. It is known in India as the “cheer” pine, and is one of the most ancient of the new growths. The Scotch fir is common on the foot-hills of the Himalayas. *P. Gerarodia*, a north-west Himalayan species, is a medium-sized tree with a conical head, growing on the more elevated parts of the mountain land. The largest of the pine trees of the Himalayas is the pine of the &quot;kauri&quot; or&quot;kauri&quot; group. It is the most ancient of the pines, the leaves are long, lax, and of a bright green tint; the cone-scales are without spines; the trunk attains a large size, and yields good and durable timber. The beautiful Monterey pine, *P. insignis*, distinguished from the other yellow pines by its more slender form, is a tufted three or four; the lower cone-scales have recurved points. This fine pine has been planted in the south-west of England, but is not commonly seen.

The pines with five leaves in each tuft have generally deciduous sheaths. The most important economic species is the well-known white pine, *P. Strobus*, from its large growth and abundance, as well as the great use made of its wood. It is one of the most important of North American timber trees. The tree abounds from Canada to Georgia, but in the eastern states it has been so long sought for by the lumberer that most of the old trees have long disappeared, and large white pine timber is now only found in quantity in the Canadian Dominion. Formerly Maine and Vermont were celebrated for the size of their pines, but few of these great trees now exist in New England. On a deep rich soil *P. Strobus* attains a height of 300 ft. and a trunk of 14 ft. in diameter; the largest known was on the estates of the Lord Montagu at Ste. Croix, near Grenville, and attains 300 ft. in height and 2 ft. and 1 to 2 ft. broad; the male catkins are of a bluish tint; the cones ripen in the autumn of the second year. The wood of the white pine is durable for indoor use, especially when protected by paint, and is much used for firkins, box, panels, etc., while it is also exposed to the weather in the construction of lattice-work, and, being covered with water, is but little injured by dry rot; it is said to be best when grown on sandy soils. Immense quantities are still exported, especially from Canada, its smooth easily-worked grain rendering it a favourite wood for the house carpenter. Like the American black pine, it is also used in the vicinity of Philadelphia and New York, where it is generally known as the “Weymouth pine,” it succeeds well on deep light soils when well-drained; trees have attained occasionally a height of 100 ft. and upwards in British plantations; in the counties of Northumberland and Yorkshire it grows well. The climate of Scotland
appears less suitable for it, probably from the want of summer heat, and it can hardly be recommended for British planting otherwise than for ornamental purposes.

Nearly approaching this is *P. excelsa*, the Bhutan pine, which differs chiefly in its longer cones and dropping glaucous foliage. It is quite unlike the *K. Kanian* and on some of the Nepal ranges, but does not grow in the most moist parts of the Sikkim Himalayas, is found at a height of 7000 to 12,000 ft., and attains large dimensions; the wood is highly resinous, and is said to be durable; great quantities of white clear gum exude from the branches when injured. The Bhutan pine is quite hardy in southern England, and has been largely planted of late as an ornamental tree.

*P. Lambertiana*, the giant pine or sugar pine of California, is the largest of the genus, rising to the height of 200 ft., with trunks 20 to 30 ft. in girth, and, it is said, occasionally attaining much larger dimensions. The head is of a pyramidal form, the lower branches drooping like those of a Norway spruce; its foliage is of a bright green colour. The pendent cones are very large, sometimes 18 in. long and 4 in. in diameter, with large nut-like seeds, which, pounded and baked, are eaten by the Indians. The tree abounds in some sandy districts, but more generally occurs singly or in small groups dispersed through the woods, attaining its greatest dimensions in light soils. The wood is soft and nearly white, but contains much resin, which when fire has run through the forest exudes, and, having in this half-burnt condition a sweetish taste, has given the common name to the tree; it is supposed to be formed slowly; from its smooth grain it is valued for indoor carpentry; the saccharine burnt resin is used as a laxative in California.

*P. Cembra* is the stone pine of Siberia and central Europe. It abounds on the Alps, the Carpathians and the Siberian ranges, in Switzerland being found at an altitude of 4000 to 6000 ft. It is a tall, straight-growing tree, with grey bark and whorls of horizontal branches giving a cylindeo-conical outline; the leaves are short, rigid and glaucous; the cones, oblong and ratherpointing upwards, grow only near the top of the tree, and ripen in the second autumn; the seeds are city like those of *P. Pinsa*, and are eaten both on the Alps and by the inhabitants of Siberia; a fine oil is expressed from them which is used both for food and in lamps, but, like that of the Italian pine, it soon turns rancid. The growth of *P. Cembra* is slow, but the wood is of remarkably even grain, and is employed by the Swiss wood-carvers in preference to any other. The *Cembra* is the "zirbel" or "zirbel-kiefer" of the Germans, and is known locally as the "mountain pine," the "arole," "aroche," etc. *P. occidentalis*, a five-leaved pine with pale-green foliage and small ovate cones, is found on the high mountains of Santo Domingo and Cuba. Many members of the group occur on the Mexican isthmus, of which, *P. cembroides*, produces edible seeds; another, *P. Montesanae*, is a valuable timber tree. *P. Ayacucho*, the common white pine of Mexico, spreads southwards on to the mountains of Guatemala, it is a large tree with glaucous foliage like *P. Strobus*, and yields a valuable resin. *P. filifera* and *P. macrophylla*, likewise natives of Central America, are remarkable for the extreme length of their leaves; the former is said to attain a large size.

(C. F. J.)

PINE-APPLE. The pine-apple so called consists in reality of the inflorescence of the plant, the originately separate flowers of which, together with the bracts supporting them, become fleshy and united in the form of a mass, the tissues take place after the process of fertilization, and it may be that the richly perfumed succulent mass is an aid in the distribution of seed by affording food to certain animals. In the highly developed cultivated pines, however, it frequently happens that the seeds do not ripen properly. The pine, *Ananas sativus*, is a member of the natural order Bromeliaceae, of tropical American origin, where it is widely spread; and it is now naturalized in the tropical regions of the Old World.

Evelyn in his *Diary* mentions tasting a pine-apple from Barbados at the table of Charles II., and this is we believe the first mention of the fruit in English literature. A picture, of which a copy may be seen at the rooms of the Royal Horticultural Society of London, represents the royal gardener, Mr. Rose, presenting on bended knee the first pine-apple grown in Britain, and it is surmised that this may have been grown from the "suckers" of the fruit above alluded to by Evelyn, though it is generally considered that the pine was not cultivated in England till 1712. For many years pine-apples were cultivated in large private gardens, but owing to the great developments in culture in the West Indies, the Azores, Canary Islands, &c., they are no longer cultivated in Britain or Europe.

PINE BLUFF, a city and the county-seat of Jefferson county, Arkansas, U.S.A., situated at an altitude of about 200 ft. in the alluvial bottoms of the Arkansas river, about 107 m. from its mouth, and about 42 m. S. by E. of Little Rock. Pop. (1910), 15,102. It has an active river trade with St. Louis, Memphis and New Orleans, and five railway outlets—the Missouri Pacific and its branch, the Pine Bluff & Western, and the St Louis South-Western and its two branches, the Pine Bluff & Arkansas River and the Altheimer. The city has many schools, and a business college, the state normal school for negroes, and Merrill institute, endowed by Joseph Merrill of Pine Bluff with $100,000. Large quantities of cotton and lumber are shipped from the city. Among the manufactures are cotton-seed oil, lumber and staves, and furniture. Pine Bluff has shops of the St Louis South-Western railway. The city's factory products were valued at $2,980,242 in 1905, an increase of 94% over their value in 1900. Pine Bluff was laid out in 1832 and chartered as a city in 1885.

PINEL, PHILIPPE (1745-1826), French physician, was born at the château de Rascas, Saint-André, in the department of Tarn, France, on the 20th of April 1745. He studied at Lavaur and afterwards at the university of Toulouse, where he took his doctor's degree in 1773. From Montpellier he removed in 1778 to Paris, engaging there chiefly in literary work connected with his profession. His first publication was a French translation of William Cullen's *Nosology* (1783); it was followed by an edition of the works of G. Bagliivi (1788), and in 1791 he published a *Traité médico-philosophique de l'aliénation mentale*. In 1792 he became head physician of the Bicêtre, and two years afterwards he received the corresponding appointment at the Salpêtrière, where he began to deliver a course of clinical lectures; these formed the basis of his *Nouveau philosophical* (1798; 6th ed., 1818), which was further developed in *La Médecine clinique* (1802). Pinel was made a member of the Institute in 1803, and soon afterwards was appointed professor of pathology in the École de Médecine. His fame rests entirely upon the fact that he was among the first to introduce the humane treatment of the insane. He died at Paris on the 26th of October 1826.

PINERO, SIR ARTHUR WING (1855- ), English dramatist, was born in London on the 24th of May 1855, the son of John Daniel Pinero, a Jewish solicitor, whose family was of Portuguese origin, long established in London. A. W. Pinero was engaged in 1874 as an actor at the Theatre Royal, Edinburgh, and came to London in 1876, to play at the Globe Theatre. Later in the year he joined the Lyceum company, of which he remained a member for five years. The first piece of his to see the footlights

PINE-APPLE—PINERO

---

PINE-APPLE (Ananas sativus) much reduced.
was £200 a year, played in October 1877 at the Globe Theatre for the benefit of Mr F. H. Macklin. The first play to make a hit was *The Money Spinner* (Theatre Royal, Manchester, Nov. 1880); but in *The Squire* (St James's Theatre, Dec. 1881) he attempted serious drama, and gave promise of the qualities of his later work. In 1883 and 1884 Pinero produced seven pieces, but the most important of his works at this period were the successful farces produced at the Court Theatre: *The Magistrate* (March 1885), which ran for more than a year; *The Schoolmistress* (March 1886); *Dandy Dick* (Jan. 1887), revived in February 1900; *The Cabinet Minister* (April 1890), and *The Amazons* (March 1893). Two comedies of sentiment, *Sweet Lavender* (Terry's, March 1888) and *The Weaker Sex* (Theatre Royal, Manchester, Sept. 1888), met with success, and *Sweet Lavender* has enjoyed numerous revivals. With *The Profligate* (Garrick, April 1889) he returned to the serious drama which he had already touched on in *The Squire*. Out of deference to the wishes of John Hare the play was fitted with the conventional "happy ending," but the original dénouement was restored, with great advantage to the unity of the play, in the printed version *The Second Mrs Tanqueray* (St James's, May 27, 1893) dealt with the converse of the question propounded in *The Profligate*, but with more art and more courage. The piece aroused great discussion, and placed Pinero in the front rank of living dramatists (see DRAMA: Recent English). It was translated into French, German and Italian, and the part of Paula Tanqueray, created in the first place by Mrs Patrick Campbell, attracted many actresses, among others Eleonora Duse. His later plays were *The Notorious Mrs Ebbsmith* (Garrick, March 13, 1893), *The Benefit of the Doubt* (Comedy, Oct. 1895), *The Princess and the Butterfly* (St James's, April 7, 1897), *Treadway of the Wells* (Court, Jan. 30, 1898), *The Gay Lord Quez* (Globe, April 8, 1899), *Iris* (Garrick, Sept. 21, 1901), *Letty* (Duke of York's, Oct. 8, 1903), *A Wife Without a Smile* (Wyndham's, Oct. 9, 1904), *His House in Order* (St James's, Feb. 1, 1906), *The Thunderbolt* (St James's, May 9, 1906) and *Mid-Channel* (St James's, Sept. 2, 1909). Pinero was knighted in 1900.

His *Plays* (11 vols. 1891-1895) have prefaces by M. C. Salaman. See also H. Hamilton Fyle, *A. W. Pinero* (1902).

**PINELO**—PINEROLO, a city and episcopal see of Piedmont, Italy, in the province of Turin. *Pop.* (1991), 12,680 (town); 18,529 (commune). It is built on a hill-side just above the valley of the Chisone and the Tanaro, at a height of 1234 ft. 24 m. by rail S.W. of Turin. The railway goes on to Torre Pellice; and steam tramways run from Pinero to Perosa, and to Cavour and Saluzzo. Till 1606 it was strongly fortified with a citadel on Santa Brigida, a castle on S. Maurizio, and city walls constructed by Thomas I. of Savoy. It has a cathedral (St Donatus), the palace of the princes of Acacia and other buildings of some interest. Cotton, silk, wool and hemp are among the local manufactures.

Pinero was bestowed on the bishops of Turin by Otto III. in 966; but in 1078 the countess Adelaide made it over to the Benedictine abbey of Santa Maria, in whose possession it remained till 1159. Thomas I. of Savoy captured the castle in 1188, and in 1246 the commune formally recognized the supremacy of Savoy. Passing in 1295 into the hands of Philip, son of Thomas III., Pinerole became his residence and capital, a distinction which it retained under Amadeus VIII. of Savoy. Francis I. of France obtained possession of the town in his descent into Italy, but Emmanuel Philibert received it back from Henry III. in 1574. A second occupation by the French occurred under Cardinal Richelieu; the French language was imposed on the people, great fortifications were constructed, and the fortress (Pinerole) was used as a state prison for such men as Fouquet, De Caymore and the Man with the Iron Mask (see IRON MASK). Victor Amadeus bore the town in 1603, and ultimately compelled Louis XIV. to renounce his pretensions on it; but before the withdrawal of the French troops the defences were demolished. In 1748 the town was made a bishop's see.

**PIN-EYED**, a botanical term for flowers which occur in two forms, one of which shows the stigma at the mouth of the corolla, as in the primrose; the term is contrasted with thrum-eyed.

**PING-PONG**, or Table-Tennis, a miniature variety of lawn-tennis played on a table, which may be of any size not less than 53 ft. long by 3 ft. broad. Various attempts were made to adapt lawn-tennis to the house, but the real popularity of the game began when, near the close of the 19th century, celluloid balls were introduced, and the game was called ping-pong from the sound of the balls as they were struck by the racket or rebounded from the table. In 1900 the ball was improved and made heavier, and for the next two years ping-pong enjoyed a popularity never before attained by a game in so short a time, not only in Great Britain but in France, the British Colonies and America. Two leagues were formed, the "Table-Tennis Association" and the "Ping-Pong Association," whose laws were practically identical. The regular tournament table is 9 ft. long by 5 ft. broad, and the net is a little less than 7 in. high. The balls, which are of hollow celluloid, are about 3½ in. in diameter. The racket has a blade, shaped like a lawn-tennis racket, about 6½ in. long and a handle long enough to grasp comfortably, all in one piece. The rackets are made either wholly of wood covered with vellum, cork, sand-paper or rubber, or of light frame covered with vellum or some other material. The table was at first marked out in courts, but is now plain. It should be unpollished and stained. In serving, a player must stand directly behind his end of the table and use an underhand motion only. The ball must clear the net and strike the table anywhere on the other side. The game is then continued until the ball misses the table or fails to pass over the net. Only one service is allowed, except in case of a let. The scoring is the same as in lawn-tennis.

See *Ping-Pong*, by Arnold Parker (London, 1902); *Table Tennis*, by A. Sinclair (London, 1902).

**PINK**, in botany, the common name corresponding to a genus of Caryophyllaceae, the Dianthus of botanists. It is characterized by the presence of simple leaves borne in pairs at the thickened nodes, flowers terminating the axis and having a tubular calyx surrounded by a number of overlapping bracts, a showy corolla of five free long-stalked petals, ten stamens proceeding, together with the petals, from a short stalk supporting the ovary, which latter has two styles and rips into a cylindric or oblong pod-like one-chambered many-seeded capsule which opens at the apex by four cults or valves. The species are herbageous perennials of low stature, often with very showy flowers. They are chiefly natives of the Mediterranean region, being few being found in temperate Asia and South Africa. The four species are wild in Britain. Of these, *D. armeria*, Deptford pink and *D. deltoides*, maiden pink, are generally distributed, *D. caesius*, Cheddar pink, occurs only on the limestone rocks at Cheddar. Two others, *D. plumarius* and *D. caryophyllus*, are more or less naturalised, and are interesting as being the originals of the pinks and of the carnations and picotees of English gardens. Garden pinks are derivatives from *Dianthus plumarius*, a native of central Europe, with leaves rough at the edges, and with rose-coloured or purplish flowers. The use of "pink" for a colour is taken from the name of the plant.¹

¹ The etymology of "pink" is disputed; it may be connected with the "pink" (apparently a naturalized form of "pick") property to prick or pinch in a manner, "pinch" of ornament, hence, later, to scalp or cut a pattern in the edge of the material. The flower has jagged edges to the petals, but the name occurs in the 16th century, and the later meaning, "to scalp," not till the 19th. Others connect with "pink," half-shut blinking of the eyes, as in "plumpie Baceius, with pinke eye" (Shakespeare *Ant. and Cl. II. vii. 121*); this word is seen in *Dianthus" (from Latin *Dianca*), to which refer this kind of flower with connected with "pinch." The French name for the flower, *oeillet*, little ear, points to that derivation. The disease of horses, known as "pink-eye," a contagious inflamation, is so-called from the colour of the inflamed conjunctiva, a symptom of the affection.
have the margin of the petals entire, and which are well marked in the centre with bright crimson or dark purple. Its grassy but glaucous foliage is much like that of the carnation, but the whole plant is smaller and more tufted. Pinks require a free loamy soil deeply trenched, and well enriched with cow-dung. They are readily increased by cuttings (pipings), by layers and by seed. Cuttings and layers should be taken as early in July as practicable. The former should be rooted in a cold frame or in a shady spot out of doors. When rooted, which will be about August, they should be planted 4 in. apart in a nursery bed, where they should be watered and shaded during the early part of October. The chief attention required during winter is to press them down firmly should they become lifted by frosts, and in spring the ground should be frequently stirred and kept free from weeds. The pink is raised from seeds, not only to obtain new varieties, but to keep up a race of vigorous-growing sorts. The seeds may be sown in March or April in pots in a warm frame, and the young plants may be pricked off into boxes and sheltered in a cold frame. They should be planted out in the early part of the summer in nursery beds, in which, if they have space, they may remain to flower, or the alternate ones may be transplanted to a blooming bed in September or the early part of October; in which case they will bloom the following summer. These will grow in any good garden soil, but the richer it is the better.

The border varieties are useful for forcing during the early spring months. These are propagated from early pipings and grown in nursery beds, being taken up in October, potted in a rich loamy compost, and wintered in a cold pit till required for the forcing house.

The following varieties are among the best. For borders and forcing: Acidilis, Carmen, Delicia, Dorothea, Her Majesty, Hercules, Lady Boleyn, Lady Blanche, Mrs Sinkins, Mrs James Welsh, Pilrig Park, Rubens, Snowden, Tom Welsh. Florists' show and bed varieties: Attraction, Beauty of Bath, Clara, Creatura, Ensign, Hesperis, John Ball, Malcolm Dunn, Mrs D. Gray, Reliance, William Paul.

The Carnation (q.c.) and Pioette are modifications of Dianthus Caryophyllus, the Couch Pink. This is a native of Europe, growing on rocks in the south, but in the north usually found on old walls. Its occurrence in England on some of the old Norman castles, as at Rochester, is supposed by Canon Elliscombe to indicate its introduction by the Normans; in any case the plant grows in similar situations in Normandy. The carnation includes those flowers which are streaked or striped lengthwise—the pioettes are those in which the petals have a narrow band of colour along the edge, the remainder of the petal being free from stripes or blotches. Those of this class were called "yellow flowers." The Sweet William of gardens is a product from Dianthus barbatus. The Sea-Pink, or Thrift, Statice Armeria (Armeria vulgaris), is a member of the same family as Plumbago; it is a widely distributed plant, and on rocky and stony sea-shores it is found in colonies. There are many improved varieties of it now in cultivation, one with almost pure white flowers.

PINKERTON, ALLAN (1819-1884), American detective, was born in 
Glasgow, Scotland, on the 25th of August 1819. His father, a 
sergeant of the Glasgow municipal police, died in 1828 
of injuries received from a prisoner in his custody. In 1824 
Allan emigrated to Chicago, Illinois. In 1834 he removed to 
Dundee, Kane county, Illinois, where he established a 
coopering business. Here he ran down a gang of counterfeiters, 
and immediately afterwards of Kane county, and 
immediately afterwards of Cook county, with headquarters in 
Chicago. There he organized a force of detectives to capture 
thieves who were stealing railway property, and this organization 
developed in 1852 into Pinkerton's National Detective Agency, 
of which he took sole charge in 1853. He was especially 
successful in capturing thieves who stole large amounts from express 
companies. In 1866 his agency captured the principals in the 
thief of $700,000 from Adams Express Company safe on a train of 
the New York, New Haven & Hartford railway, and recovered 
all but about $120,000 of the stolen money. In February 1861 
Pinkerton found evidence of a plot to assassinate President-elect 
Lincoln upon his arrival in Baltimore on his way to Washington; 
as a result, Lincoln passed through Baltimore at an early hour 
in the morning without stopping. In April 1861 Pinkerton, on 
the suggestion of General George B. McClellan, organized a 
system of obtaining military information in the Southern states. 
From this system he developed the Federal secret service, of 
which he was in charge throughout the war, under the assumed 
american merchant for damage through "irregular or illegal captures
or condemnations," and during this time adjusted on behalf of Maryland a claim of the state to stock in the Bank of England. In May 1806, with James Monroe, then minister at London, he was commissioned to treat with the British government concerning the capture of neutral ships in time of war; in 1807–1811, after Monroe's return to America, he was resident minister in London. He was elected to the Maryland senate in September 1811, and from December 1811 to January 1814 was attorney-general of the United States. In August 1814 he was wounded at Bladensburg. He served in the National House of Representatives in January–April 1816, and in 1816–1818 was minister plenipotentiary to Russia and special minister to Naples, where he attempted to secure indemnity for the losses to American merchants by seizure and confiscation during the rule of Murat in 1809. From 1820 until his death, at Washington, on the 25th of February 1822, he was a member of the United States Senate. He was a member of the conference committee on the bill for the admission of Maine and Missouri, which in its final form embodied what is known as the Missouri Compromise. Pinney was a remarkably able lawyer and an orator of the old school. See The Life of William Pinckney (New York, 1853) by his nephew, William Pinckney (1810–1883), who was Protestant Episcopal bishop of Virginia in 1879–1883; and Henry Wheaton, Some Account of the Life, Writings, and Speeches of William Pinckney (New York, 1853). The last name of two types of vessel or boat, one a light sailing vessel with two schooner-rigged masts, the other a heavy eight-oared man-of-war's boat. The word is usually referred to Lat. pinus, pinus, but this derivation is at variance with the earlier form "spinae." PINNACLE (from Lat. pinnaculum, a little feather, pinnis; the Gr. πηγκειν, diminutive of πτερός, wing, is also used in this sense), an architectural ornament originally forming the cap or crown of a buttress or small turret, but afterwards used on parapets at the corners of towers and in many other situations. Some authors assert that there are no pinnales in Romanesque styles, but conical caps to circular buttresses, with finial terminations, are not uncommon in France at very early periods. Viollet-le-Duc gives examples from St. Germer and St. Remi, and there is one of similar form at the west front of Rochester Cathedral. In the 12th-century Romanesque two examples have been cited, one from Bredon in Worcestershire, and the other from Cleeve in Gloucestershire. In these the buttresses run up, forming a sort of square turret, and crowned with a pyramidal cap, very much like those of the next period, the Early English. In this and the following styles the pinnacles seem generally to have had its appropriate uses. It was a means to counteract the thrust of the vaults, particularly when there were flying buttresses; it stopped the tendency to slip of the stone copings of the gables, and counterpoised the thrust of spires; it formed a pier to steady the elegant perforated parapets of later periods; and in France especially served to counterbalance the weight of overhanging corbel tables, huge gargoyles, &c. In the Early English period the small buttresses frequently finished with gables, and the more important frequently with pinnales supported with clustered shafts. At this period the pinnales were often supported on these shafts alone, and were open below; and in larger work in this and the subsequent periods they frequently form niches and contain statues. About the Transition and during the Decorated period, the different faces above the angle shafts often finish with gables. Those of the last-named period are much richer, and are generally decorated with crockets and finials, and sometimes with ballflowers. Very fine groups are found at Beverley Minster and at the rise of the spire of St Mary's, Oxford. Perpendicular pinnales differ but little from Decorated, except that the crockets and finials are of later character. They are also often set angle-ways, particularly on parapets, and the shafts are pannelled. In France pinnales, like spires, seem to have been in use earlier than in England. There are small pinnales at the angles of the tower in the abbey of Saints. At Roulet there are pinnales in a similar position, each composed of four small shafts, with caps and bases surmounted with small pyramidal spires. In all these examples the towers have semicircular-headed windows.

PINNOCK, WILLIAM (1782–1843), English publisher and educational writer, was born at Alton, Hampshire, on the 3rd of February 1782, and was at first a schoolmaster, then a bookseller. In 1817 he went to London and, in partnership with Samuel Mander, began to publish cheap educational works. The firm's first productions were a series of Catechisms, planned by Pinnoch, consisting of short popular manuals, arranged in the form of question and answer, of the different departments of knowledge. They were followed by abridged editions of Goldsmith's histories of England, Greece and Rome, and a series of county histories which were no less profitable. Pinnoch lost nearly all his money in outside speculation, and died in London on the 21st of October 1843. His son, William Henry Pinnock (1813–1885), a clergyman, was the editor and author of several elementary textbooks and scriptural manuals, and of various works on ecclesiastical law and usage.

PINNOCHLE, or PUNCHOLE (Ger. Pinochel or Binochel, of uncertain etymology), a game of cards probably invented by Germans in the United States about the middle of the 19th century. It bears a general resemblance to Bézique (q.v.), and has almost entirely superseded the other games of the same family in America. Pinochle may be played by two, three, or four persons. Two packs, from which all cards below the nines have been deleted, are shuffled together, forming one pack of 48 cards. The object of the game is to make 1000 points. The cards rank as follows: ace 11, ten 10, king 4, queen 3, knave 2. The nine counts nothing unless it be turned for trumps, when it scores 10. The last trick scores 10. The term "to meld" (Ger. melden, to announce), as used in pinochle, means "to declare." "Melds" are combinations which are declared during the play of the hands. They are of three classes: (1) marriage, (2) and 'pinochles,' (3) "fours." The "melds" of the first class include marriage (king and queen of any plain suit), royal marriage (king and queen of trumps), sequence (the five highest trumps), 150. In the second class the "melds" are "pinochle" (queen of spades and knave of diamonds), "double pinochle" (both queens of spades and knaves of diamonds), 300; "grand pinochle" (king of spades and knave of diamonds), 80; this "meld" is not often played in America. Of the third class the "melds" are: four aces of different suits, 100; four kings of different suits, 80; four queens of different suits, 60; four knaves of different suits, 40; eight aces, 1000; eight kings, 800; eight queens, 600; eight knaves, 400.

In single pinochle (two players) each player receives twelve cards, four at a time, the twenty-fifth being turned up beside the stock for trumps. The non-dealer leads a card, to which the dealer plays. There is no obligation either to take, follow suit or trump. The winner of the trick leads again, before which, however, he may "meld" any one combination he holds. After he has "melded," or refused to do so, he draws a card from the top of the stock and adds it to his hand without showing it, his adversary doing the same, so that each player continues to hold twelve cards. Playing, announcing, and drawing then go on until the stock is exhausted. All combinations "melded" must be laid face upward on the table but still belong to the player's hand, though they may not be taken up as long as the stock has not been exhausted. When the cards and documents cease, and all cards are exposed in the hands. The last twelve tricks are then played, but now both players must follow suit whenever the adversary does so, and the trick win the trick if possible, either with a superior card or a trump. A failure to do this is a "revoke" and is penalized by the loss of all points made by "cards," i.e. for the five highest cards in each suit, which after all the tricks have been counted for the player holding them. Ace counts 11 points, ten 10, king 4, queen 3, and knave 2, so that 240 points for "cards" are divided between the two players. Though points are not counted during the play, a mental count is kept whenever a player sees that, by adding the value of his "melds" to what he thinks his cards will count, he has enough to win the game, namely 1000 points, he "calls out or knocks on the table, and proceeds to expose his cards. If he fails to show enough to win, he loses the game. If neither player knows how the game continues until one of them scores 1250; if still a tie, 1500. If a player fails to make good a "meld" he is set back that number of points. The game is scored by counters or on a cribbage-board.
In three-handed pinochle the "melds" are exposed before a card is played, and no player may "meld" after he has played the first trick. A rule is sometimes made that an overlooked combination may be scored by the other players. Four-handed pinochle is played either with partners or each player for himself.

Pinsk, a town of Russia, in the government of Minsk, at the confluence of the Strumen and Pina rivers, 106 m. S.W. by rail of Minsk. Top., 27,938, two-thirds being Jews. The town carries on considerable trade, due to the navigable river Pina, which connects it with the fertile regions in the basin of the Dnieper, and, by means of the Dnieper-and-Bug canal, with Poland and Prussia, while the Oginsky canal connects it with the basin of the Niemen. Pottery, leather, oil, soap and beer are the chief products of the local industries. The draining of the marshes around Pinsk was begun by the government in 1872, and by 1897 8,000,000 acres had been drained at an average cost of 38. per acre. Pinsk (Pinsk) is first mentioned in 1092 as a town belonging to Sviatopolk, prince of Kiev. In 1132 it formed part of the Minsk principality. After the Mongol invasion of 1230-42 it became the chief town of a separate principality, and continued to be so until the end of the 13th century. In 1320 it was annexed to Lithuania; and in 1569, after the union of Lithuania with Poland, it was chief town of the province of Brest. During the rebellion of the Cossack chief, Bogdan Chmielnicki (1648), the Poles took it by assault, killing 14,000 persons and burning 5000 houses. Eight years later the town was burned by the Poles, Charles XII. took it in 1706, and burned the town with its suburbs. Pinsk was annexed to Russia in 1795.

Pinsuti, Giro (1829–1888), Anglo-Italian composer, was born at Siena, and was educated in music, for a career as a pianist, partly in London and partly at Bologna, where he was a pupil of Rossini. From 1848 he made his home in England, where he became a teacher of singing, and in 1856 he made a professor at the Academy of Music in London. He became well known as a composer of numerous favourite songs and part-songs, as well as of three operas brought out in Italy, and it is by the former that he is still remembered. His style was simple, his diction clear and direct, and his music is a characteristic example of the great coolness of judgment and decision in his work. His three-handed pinochle was in Goa, waiting for a ship to take him to Portugal, when he took a sudden resolution to enter the company of Jesus and devote a large part of the capital he had accumulated to the evangelization of Japan.

The viceroy appointed him ambassador to the king of Bungo in order to give the mission an official standing, and on the 18th of April he set sail with the provincial, Father Belchior Nunes. Owing to bad weather and contrary winds, however, the missionaries did not reach Japan until July 1556, but the success of the mission represented a notable service to the cause of Christianity and civilization. On the 14th of November 1556 Father Belchior and Mendes Pinto began their return voyage and reached Goa on the 17th of February 1557. During his stay of a twelve-month there, the latter left the company, being dispensed from his vows for want of vocation at his own request, though a modern authority states that he was expelled because he was not willing to subscribe to a movement to possess Jewish blood. He finally returned to Portugal on the 30th of September 1558, and settled at Pragal near Almada, where he married and wrote his book, the Peregrination; the MS., in fulfilment of his wishes, was presented by his daughter to the Casa Pia for penitent women in Lisbon, and it was published by the administrators in 1614. When Philip II. of Spain came to Portugal as its king, he listened with pleasure to the account of Mendes Pinto's travels, and by letter of the 15th of January 1553 gave him a pension for his services in the Indies. But the reward came too late, for the great traveller died on the 8th of February.

In the light of our present-day knowledge of the East, Pinto is regarded as having been on the whole a careful observer and truthful narrator, but this was not always the case. Some witty countryman of his own parodied his name into Ferneão, mentes? Pinto? ("Ferdinand, do you lie? I do!"); and the English dramatist Congreve only expressed the general opinion of the unlearned when he wrote in Love for Love, "Mendez Pinto was but a type of thee, thou liar of the first magnitude." It must be remembered that Pinto wrote the Peregrination long subsequent to the events he records, and this fact and a certain fertility of imagination sufficiently account for inexactitudes. Furthermore, as the book was only published posthumously, he never had the opportunity of correcting the proofs. Some of his most marvellous stories are expressly given on the authority of writers belonging to the countries he describes; others he tells from hearsay, and Oriental informants are prone to exaggeration. But if he somewhat adorned the truth, he did not wilfully misrepresent it. The book itself gives the impression of sincerity, and the editors of the first edition bear witness to the probity, good faith and truthfulness of Mendes Pinto as a man. Herrera Maldonado prefixed his Spanish translation of the Peregrination (1620) by a lengthy and erudite apology to demonstrate its authenticity, and Castillo has reinforced his guarantee by modern publishers. In the narrative portions of his work Pinto's style is simple, clear and direct, and his language rich, particularly in sea terms, and appropriate to his various subjects. There is an entire absence of artifice about the book, which must always rank as a classic, and it might fairly be argued that Mendes Pinto did for the prose of Portugal what Camoens did for its poetry; this is the more remarkable, because it does not appear that he ever received any education in the ordinary sense. He wrote the book for his children to learn to read by, and modestly excused its literary defects by alleging his rudeness and lack of talent. Tradition has it that the MS. was entrusted to the chronicler Francisco de Andrade for the purpose of being polished in style and made ready for press, but that all he did was to divide it into chapters.

The Peregrination has gone through many editions subsequent to that of 1614, and in 1865 Castillo published excerpts in his Literaria classica portugueza with an interesting notice of Mendes Pinto's life and works. Pinto's Peregrination was translated into French (3 editions), Spanish (4 editions), and in English by Henry Cogan, London (1663, 1692 and—abridged and illustrated, with introduction by Arminius Vambéry—1801). Cogan omits the chapters relating to Mendes Pinto's intercourse with, and the last days of, St Francis Xavier, presumably as a concession to anti-Catholic prejudice.

Pinto, Belchior de Almeida, Ferno Mendes Pinto (Lisbon, 1904). Ferno Mendes Pinto e o Japão (Lisbon, 1906); also Subsidios para a biografia de Ferno Mendes Pinto by Jourdan de Freitas (Coimbra, 1905).
PINTO. The remarkable brown, black and blue spots of discolouration of the whole body met with endemically in Mexico, PINTO. Among the Venetians. The name of "pinto" or "mal de los pintos," were first claimed by Gastambide (Presse med. Belge, 1881, Nos. 33-41) as due to the presence of a vegetable parasite, whose spores and even mycelial filaments may be detected among the deeper rows of cells of the retic mucosum. The disease appears to be one of the many forms of *morbus miseriae*; but it is contagious, and is sometimes seen in the well-to-do. In some villages of the western districts of Tabasco (Mexico) it has been estimated that 9% of the inhabitants suffer from the pinto; McClellan says that in 1826 in the City of Mexico he saw a whole regiment of horses suffering from this disease.

PINTURICCHIO (1454-1513), Italian painter, whose full name was BERNARDINO DI BETTI, the son of a citizen of Perugia, Benedetto or Betto di Biagio, was one of a very important group who inherited the artistic traditions and developed the style of the older Perugian painters, such as Bonfigli and Fiorentino di Lorenzo. According to Vasari he was a pupil of Perugino; and so in one sense no doubt he was, but rather as a paid assistant than as an apprentice. The strong similarity both in design and methods of execution which runs through the works of this later Perugian school is very striking; paintings by Perugino, Pinturicchio, Lo Spagna and Raphael (in his first manner) may often be mistaken one for the other. He did not follow in the execution of large frescoes, pupils and assistants had a large share in the work, either in enlarging the master's sketch to the full-sized cartoon, in transferring the cartoon to the wall, or in painting backgrounds, drapery and other accessories. After assisting Perugino in the execution of his frescoes in the Sistine Chapel, Pinturicchio was employed by various members of the della Rovere family and others to decorate a whole series of chapels in the church of S. Maria del Popolo in Rome, where he appears to have worked from 1484, or earlier, to 1492 with little interruption. The earliest of these is an altarpiece of the "Adoration of the Shepherds," in the first chapel (from the west) on the south, built by Cardinal Domenico della Rovere; a portrait of the cardinal is introduced as the foremost of the kneeling shepherds. In the lunette under the vault Pinturicchio painted small scenes from the life of St Jerome. The frescoes which he painted in the next chapel, that built by Cardinal Innocenzo Cibo, were destroyed in 1709, when the chapel was rebuilt by Cardinal Alderano Cibo. The third chapel on the south is that of Giov. della Rovere, duke of Sora, nephew of Sixtus IV., and brother of Giuliano, who was afterwards Pope Julius II. This contains a fine altarpiece of the "Madonna enthroned between Four Saints," and on the east side a very nobly composed fresco of the "Transfiguration of the Virgin." The vault, and the lunette above it, are richly decorated with small pictures of the life of the Virgin, surrounded by graceful arabesques; and the dado is covered with monochrome paintings of scenes from the lives of saints, medallions with prophets, and very graceful and powerfully drawn female figures in full length in which the influence of Signorelli may be traced. In the fourth chapel Pinturicchio painted the Four Latin Doctors in the lunettes of the vault. Most of these frescoes are considerably injured by damp, but happily have suffered little from restoration; the heads are painted with much minuteness of finish, and the whole of the pictures depend very largely for their effect on the final touchings of color. The last paintings completed by Pinturicchio in this church were the frescoes on the vault over the retro-choir, a very rich and well-designed piece of decorative work, with main lines arranged to suit their surroundings in a very skilful way. In the centre is an octagonal panel of the coronation of the Virgin, and round it medallions of the Four Evangelists—the spaces between them being filled up by reclining figures of the Four Sibyls. On each pendentive is a figure of one of the Four Doctors enthroned under a niched canopy. The bands which separate these pictures have elaborate arabesques on a gold ground, and the whole is painted with broad and effective touches, very telling when seen (as is necessarily the case) from a considerable distance below. No finer specimen of the decoration of a simple quadruplicate vault can anywhere be seen.

In 1492 Pinturicchio was summoned to Orvieto, where he painted two Prophets and two of the Doctors in the duomo. In the following year he returned to Rome, and was employed by Pope Alexander VI. (Borgia) to decorate a suite of six rooms in the Vatican, which Alexander had just built. These rooms, called after their founder the Appartamenti Borgia, now form part of the Vatican library, and five of them still retain the fine series of frescoes with which they were so skillfully decorated by Pinturicchio. The upper part of the walls and vaults, not only covered with painting, but further enriched with delicate stucco work in relief, are a masterpiece of decorative design and execution. According to Vasari, the upper part of the upper stories contains ornament which is not much better model for imitation in that respect than the more celebrated Stanze of Raphael immediately over the Borgia rooms. The main subjects are: (1) the Annunciation, the Nativity, the Magi, and the Resurrection; (2) Scenes from the lives of St Catherine, St Antony and other saints; (3) allegorical figures of music, arithmetic and the like; (4) four figures in half length, with rich arabesques; (5) figures of the planets, the occupations of the various months, and other subjects. The sixth room was repainted by Perino del Vaga.

Though not without interruption, Pinturicchio, assisted by his pupils, worked in these rooms from 1492 till 1498, when they were completed. His other chief frescoes in Rome, still existing in a very genuine state, are those in the Cappella Bufalini at the south-west of S Maria in Ara Coeli, probably executed from 1497 to 1500. These are well-designed compositions, noble in conception, and finished with much care and refinement. On the altar wall is a grand painting of St Bernardino of Siena between two other saints, crowned by angels; in the upper part is a figure of Christ in a vesica-glory, surrounded by angel musicians; on the left wall is a large fresco of the miracles done by the corpse of St Bernardino, very rich in colour, and full of very carefully painted heads, some being portraits of members of the Bufalini family, for whom these frescoes were executed. One group of three females, the central figure with a child at her breast, is of especial beauty, recalling the grace of Raphael's second manner. The composition of the main group round the saint's corpse appears to have been suggested by Giotto's painting of St Francis on his bier in S. Croce at Florence. On the vault are four noble figures of the Evangelists, usually attributed to Luca Signorelli, but certainly, like the rest of the frescoes in this chapel, by the hand of Pinturicchio. On the vault of the sacristy of S. Cecilia in Trastevere, Pinturicchio painted the Almighty surrounded by the Evangelists. During a visit to Orvieto in 1496 Pinturicchio painted two more figures of the Last Doctors in the choir of the duomo—now, like the rest of his work at Orvieto, almost destroyed. For these he received fifty gold ducats.

Among his panel pictures the following are the most important. An altarpiece for S Maria de' Fossi at Perugia, painted in 1496-1508, now moved to the picture gallery, is a Madonna enthroned among Saints, graceful and sweet in expression, and very minutely painted; the wings of the retable have standing figures of St Augustine and St Jerome; and the predella has paintings in miniature of the Annunciation and the Evangelists. Another fine altarpiece, similar in delicacy of detail, and probably painted about the same time, is that in the cathedral of San Severino—the Madonna enthroned looks down towards the kneeling donor. The angels at the sides in beauty of face and expression recall the manner of Lorenzo di Credi or Da Vinci. The Vatican picture gallery has the largest of Pinturicchio's panels—the Coronation of the Virgin, with the apostles and other saints below. Several well-executed portraits occur among the kneeling saints. The Virgin, who kneels at Christ's feet to receive her crown, is a figure of great tenderness and beauty, and the lower group is composed with great skill and grace in arrangement. Other important panel paintings by Pinturicchio exist

in the cathedral of Spello, in the Siena gallery, at Florence, at Perugia, and in other collections.

In 1501 Pinturicchio painted several fine frescoes in S. Maria Maggiore at Spello—all very decorative and full of elaborate and architectural accessories. One of these, the Annunciation, is signed "Bernardinos Pinturicchius Persinvs." The most striking of all Pinturicchio's frescoes, both for brilliance of colour and their wonderful state of preservation, are those in the cathedral library at Siena, a large room built in 1495 by Cardinal Francesco Piccolomini, afterwards Pius III. In 1502 the cardinal contracted with Pinturicchio to decorate the whole room with arabesques on the vault, and on the walls ten scenes from the life of Acenae Sylvius Piccolomini, Pius II., the uncle of Cardinal Francesco.

The contract specially provided that the cartoons, their transfer on to the walls, and the heads, were to be by Pinturicchio's own hand, thus contradicting Vasari's assertion that the cartoons were the work of Raphael. The document provides for the price of these frescoes, namely one thousand gold ducats, to be paid in various installments. The work was begun early in 1503, but was interrupted for a while by the death of Pius III. His will, however, provided for the completion of the work by his executors, and the whole series was finished in 1505. The subjects are: (1) the journey of the young Sylvius Piccolomini to the Council of Basel, in the suite of Cardinal Capranica; (2) his reception by James I. of Scotland as envoy from the Council of Basel; (3) his being crowned as laurel by the Cardinal of Pisa; (4) his return to Rome by Pope Eugenius IV. as ambassador from Frederick III.; (5) outside the wall of Siena he presents to Frederick III. his bride Leonora, infant of Portugal; (6) he receives the cardinal's hat from Pope Calixtus II.; (7) he is in Rome, and after his elevation to Pius II.; (8) he presides at a council at Mantua; (9) he canonizes St. Catherine of Siena; (10) he arrives in Ancona to promote the crusade against the Turks. In addition to these there is, outside the door, the coronation of Pius III. In the lower part of the scene of St. Catherine's canonization he has introduced his own portrait, and standing by him is a youth who bears some resemblance to Raphael.

In 1508 Pinturicchio painted another panel of the Madonna enthroned among saints for the church of the Minori Commonali at Spello, over the altar of the sacristy. On his return to Siena he painted a whole series of frescoes on the walls of the Palazzo Petrucci, now all destroyed except one scene of the return of Ulysses to Penelope (or possibly Cottinatis and Lucrétia), which is now in the National Gallery of London, transferred to canvas. One of his last works, painted in 1513, the year of his death, is a very beautiful and highly finished panel with Christ bearing His Cross, now in the Palazzo Borromeo in Milan. Pinturicchio married Grania di Nicco1, and had by her two sons and four daughters; there is probably no truth in the story of his being starved by his wife during his last illness.

Pinturicchio's worth as a painter has been for the most part undervalued, partly owing to the very strong prejudice and dislike which tinged Vasari's biography of him. Even Crowe and Cavazzacase hardly did him justice. A fairer estimate of his position in the history of art is given by Vermiglioli, Memorie di Pinturicchio (Perugia, 1846); and in the valuable notes and appendix of Milanesi's edition of Vasari, iii. 493-531 (Florence, 1878). See also Schmarsow, Raphael and Pinturicchio in Siena (Stuttgart, 1880), and Pinturicchio in Rome (Stuttgart, 1882), both well illustrated by photo-lithography.

PINWELL, GEORGE JOHN (1842-1875), British water-colour painter, was born at Wycombe, and educated at Heatherley's Academy. He is one of the most interesting personalities in the little group of water-colour painters which included Frederick Walker and A. B. Houghton, a group whose style was directly derived from the practice of drawing upon wood for book illustration. He was one of the most delightful book lovers of his day, poetic in imagination, and the whole sense of colour. As he died young his works are few, but their promise was so great that had he lived he would probably have attained a very high position. His early life was one of considerable privation. In 1862 he entered at Heatherley's studio and there obtained his art education. His earliest drawings appeared in Liliiput Leide. He did a little work for Fun and executed several designs for the silversmiths, Elkingtons. In 1863 his first drawing appeared in Once a Week, and from that time his work was in constant demand. There are many of his compositions in Good Words, The Sunday Magazine, The Quiver and London Society, but his most important works made for the Dalziel brothers were illustrations of Goldsmith, of Jean Ingelow's poems, Robert Buchanan's Ballads of the Affections, and the Arabian Nights.

Of Pinwell's pictures in colour, which are distinguished by a remarkable, jewel-like quality and marked by his strong love of pure, bright colour and opalescent effect, the chief are the two scenes from the Pied Piper of Hamelin, Gilbert à Becket's Troth, Of Tune or The Old Cross, A Seat in St James's Park, and The Elixir of Life.

In 1874 Pinwell fell seriously ill and went to Africa for the winter. He painted several remarkable pictures at Tangier, but his strength gradually broke down and he died, aged 32, in his wife's arms on the 7th of September 1875. Pinwell was an exhibitor at the Dudley gallery, and in 1869 was elected associate of the Royal WaterColour Society and full member in 1870; to this gallery he contributed fifty-nine works. A posthumous exhibition of his works was held in 1876 in Bond Street.

See Life of George J. Pinwell, by George C. Williamson, 1900. (G. C. W.)

PINZON, a family of wealthy Spanish navigators, of Palos in Andalusia, three members of which—Martin Alonzo, Francisco and Vicente Yáñez, brothers—were associated with Columbus in the discovery of America.

Alonzo Pinzón, born about the middle of the 15th century, gave material assistance to Columbus in carrying out his project. "If Colon was the head, Pinzón was the right arm" (Asensio). In the expedition of 1492 he commanded the "Pinta," on which his brother Francisco was pilot; another brother, Vicente Yáñez, commanded the "Nina." On the 6th of October Martin Alonzo suggested to Columbus (when already in the longitude of the Bermudas) to change the course of the expedition from due west to south-west; on the 7th of October this suggestion—strengthened by the observation of a flight of birds to the south-west—was adopted, bringing the fleet, four days later, to the landfall at Guanahani (San Salvador, Watling Island) in the Bahamas (Oct. 12, 1492). On the 21st of November 1492, near the east end of the north coast of Cuba, Martin Alonzo left Columbus, making eastward in search of the gold-land of which they had heard the natives speak. On the 6th of January 1493 he rejoined the admiral, who accepted his excuses. But on the return journey he again left his leader, and when Columbus arrived at Palos on the 15th of March 1493 he learned that Alonzo had already landed at Bayona in Galicia. If his object was to forestall Columbus and pose as discoverer of the New World, he was foiled; audience was refused him by Ferdinand and Isabella; and soon after he died, perhaps of chagrin.

Vicente Yáñez Pinzón, who commanded the "Nina," in 1492-1493, also gave Columbus material help, and remained loyal to his leader throughout. In after years he made important discoveries on his own account. Late in December 1499 he sailed with four caravels across the Atlantic to the south-west, and on the 7th of February 1500 he struck the South American continent at Cape S. Agostinho, near its most easterly projection (called by him Cape Santa Maria de la Consolacion) almost three months before the Portuguese navigator Cabral reached Brazil, the discovery of which is generally attributed to him. Proceeding southwards a short distance, he then turned north, followed the coast to the north-west, discovered the Amazon estuary, and went as far as what is now Costa Rica. After touching at Haiti, and losing two of his vessels among the Bahamas, Vicente returned to Palos in the end of September 1500. Although concessions were made to him, and he was created governor of the newly discovered lands by Ferdinand and Isabella, he does not seem to have ever taken possession. In 1507 we find Vicente sailing with Juan Diaz de Solis along the east coast of Central America. In 1520, again with De Solis, he coasted the Atlantic side of South America as far as the La Plata estuary, hoping to find an opening westwards leading to the Spice Islands. According to Herrera, he even reached 40°S.
passing the La Plata without recognizing it, and turning back about the 3oth of the month, to the Rio Negro, but this is probably an exaggeration. After 1523 all traces of Vicente are lost.

XIV, ch. ii.; bibliography in Joaquin Caetano da Silva's L'Oyapock et l'Amazonie (Paris, 1861); Herrera, Indias Occid., Dec., lib. vi, cap. 17; lib. vii., caps. 1 and 9 (Madrid, 1730); Overbeck, Historie der indischen, Malay. and Arabischen (Munich, 1815, 2 vols.); Peschel, Geschicht der Erdkunde, pp. 230, 233, 249 (Munich, 1865); Zeitalter der Entdeckungen, pp. 305, &c., 426; Jose Maria Asencio, Cronicas de los viajes y descubrimientos (Barcelona, 1891); Cesareo Fernandez Duro, Colon e Pizons.

PIO DI SAVOIA, an ancient noble Italian family, first mentioned by good authorities in the 14th century. From the house of Este (q.v.) they received the lordship of Carpi, and later they acquired the fiefs of Moldava, Sassuolo, &c. Many members of the family were distinguished as condottieri, diplomats and ecclesiastics. Alberto Pio obtained from the house of Savoy in 1450 the privilege of adding "di Savoia" to his name as a reward for his military services. Another Alberto Pio (1475-1531), who was French ambassador in Rome, won fame as a man of learning, and Carolino Rodolfo Pio (1576-1664) was a trusted adviser of Pius V. He was also a learned man and helped to establish the Inquisition at Milan.

Asciano Pio (d. 1649) was a dramatic poet of some merit. Spain conferred the title of prince to the family, and one branch of it is to this day established in Spain.

See P. Litta, Le Famiglie celebri italiane (Milan); G. Camponi Memorie storiche del Marco Pio di Savoia (Modena, 1876); A. Ceriani and G. Porro, Il Roloto epistologra del principi Pio di Savoia, in their Giunti storici italiani (q.v. of this ser.); on the family, see XI. Fasc. 1, ser. III. an. VIII. 96, and ser. III. an. XIX. 493.

PIOMBINO, a seaport of Tuscany, Italy, in the province of Pisa, 8 m. by rail W.S.W. of Campiglia Marittima (which is 53 m. S.E. of Pisa), 62 ft. above sea-level, at the southern extremity of the peninsula of the Monte Massoncello. Pop. (1901), 5790 (town); 7703 (commune). It is surrounded by old walls, and contains some interesting Renaissance works by a master of about 1458 under the influence of Alberti. It is the port of embarkation for Elba, the nearest point of which is about 6 m. to the south-west, and originally belonged to Pisa. It gives the title of prince to the Buoncompagni Ludovisi family, who, however, no longer own it.

PIONEER, properly a foot-soldier (Med. Lat. pedo, pedonis, through O. Fr. peonier, pionnier, cf. "paw") who with spade, axe and other implements, precedes an army or smaller military body, and clears or makes a road, digs intrenchments, prepares a camping ground, &c. The word is thus applied to all who, actually or figuratively, are first in exploring or working an undiscovered or undeveloped country or field of inquiry.

PIOUKROW (Ger. Petrikau), a government of Russian Poland, bounded by the government of Warsaw on the N., Radom and Kielce on the E., Kattow on the W., and Prussian Silesia on the S. Area, 47230 sq. m.; pop. (1906, estimate), 1,675,200. Geologically it represents a continuation of Upper Silesia, and is built up of Upper Carboniferous deposits, containing near Bendzin a bed of coal 265 sq. m. in extent. Permian and Jurassic deposits, containing zinc ores, as also lignite and limonite iron ores, overlie the Carboniferous. The surface consists of a series of hills, 1000 to 1600 ft. above sea-level, intersected by ravines, and stretching from south-west to north-east. The government is drained by the Warta and the Pilica, and was formerly covered with thick forests. It was colonized by Mazurds and Poles (Veliko-Polans and Malo-Polans). The government, which is the most densely peopled in the Russian Empire, is divided into four provinces: Poles (south-west), Russian Silesia, Bendzin, Brzeziny, Czenstochowa, Lask, Lodz, Novo-Radom and Rawa. Agriculture and cattle-breeding are extensively carried on, and coal and iron are mined. Textile industries developed with extraordinary rapidity during the closing years of the 19th and the opening years of the 20th centuries, the towns of Lodz, Pahianice, Zgerz and Bendzin all being important centres. Other branches of productive industry are distilleries, breweries, flour-mills, brickyards, sugar, cement, glass and candle factories. Granica and Sonnowicz, in this government, are two of the most important custom-houses in Russia, and the annual trade is estimated at 5,200,000.

PIOUKROW, a town of Russian Poland, capital of the government of the same name, and formerly the seat of the high court of Poland, on the railway from Warsaw to Vinn, 90 m. south-west of the former and 5 m. west of the river Pileca. Pop. (1906), 32,173. It is a well-kept town, with numerous gardens, and has flour-mills, saw-mills, tanneries, agricultural machinery works, and breweries. One of the oldest towns in Poland, Piotrkow was in the 15th and 16th centuries the place of meeting of the diets, and here the kings were elected. In the 14th century Casimir the Great built here a castle (now a military church) and surrounded the town with walls. Here in 1769 the Russians defeated the Polish armies. Asensio, Duro, Colon e Pizon.

PIOZZI, HESTER LYNCH (1741-1821), English writer, well known as the friend (Mrs Thrale) of Samuel Johnson (q.v.), was born on the 16th of January 1741, her father being John Salusbury of Bobbey, Carnarvonshire. Her maternal uncle, Sir Robert Salusbury Cotton, contemplated providing for his niece, but he died without having carried out his intention. She and her mother lived in London, and amongst her childish recollections were meetings with James Quin and David Garrick. She received a solid education, for she was acquainted with Latin as well as with French, Italian and Spanish. In 1763 she was married to Henry Thrale, a rich Southwark brewer, whose house was at Streatham on the south-east corner of Tooting Bec Common. There was very little sympathy between the lively girl and Thrale, who was thirteen years her senior, but gradually she drew round her a distinguished circle of friends. She was introduced to Samuel Johnson in 1765 by Arthur Murphy, who was an old friend of her husband's. In 1766 Johnson paid a long visit to Streatham, and from that time was more or less domiciled at the Thrales. In time it became his custom to spend the middle of the week at Streatham, devoting the remaining days to his own heterogeneous "family." He was genuinely attached to his hostess, and thoroughly appreciated the luxury in which the Thrales lived. They were able to soften some of his eccentricities, and they certainly made him happy. He travelled with them in Wales in 1774, and in France in 1775. Dr Burney gave lessons to one of the Miss Thrales, and in 1778 he brought his daughter Fanny to Streatham. She became a warm friend of Mrs Thrale, and has left an account of the Streatham household in her diary. This friendship was by no means always unclouded. Fanny Burney was very sensitive, and sometimes thought that Mrs Thrale gave herself airs of patronage. Meanwhile, in 1772, Thrale's business was seriously injured, and he was threatened with bankruptcy. The situation was saved by his wife's efforts, and in the next year Thrale travelled, leaving her in charge of his affairs. He was twice returned for the borough of Southwark, chiefly through her efforts. In 1781 Mr. Thrale died, and Dr Johnson helped the widow with her business arrangements, advising her to keep on the brewery, until she "cured his honest heart of its incipient passion for trade, by letting him into some, and only some, of its mysteries." The brewery was finally sold for £315,000. Mrs Thrale had met Gabriele Piozzi, an Italian musician, in 1780. Johnson was now in failing health, and soon began to feel himself slighted. His suspicions were definitely aroused when she laid aside her mourning for Thrale in 1782, and the Streatham house was sold. In 1783 her engagement to Piozzi was announced. The objections of her daughters and her friends induced her to break it off for a time, but it was soon resumed, and in 1784 they were married. Johnson told Miss Burney that he desired the memory of Mrs Thrale from his mind, burning every letter of hers on which he could lay his hand. The Piozzis presently left England to travel in Italy. At Florence they fell in with Robert Merry and the other "Della Cruscan" writers ridiculed by William Gifford in his Moeauid and Davud, and she contributed some verses to their Florence Miscellany in 1785. In 1786 she published Anecdotes of the late Samuel Johnson, during the last twenty years of his life, which was severely criticized by Boswell. She was ridiculed by "Peter Pindar" in Bosay and Zoszi.
PIE

Piozzi; or the British Biographers, A Town Elloquent (1786). But though Miss Burney and some others held aloof, the Piozzi found plenty of friends when they returned to London in 1787. Piozzi died at Bynonnella, a villa she had built on his wife's Carnarvonshire estate in 1809, and Mrs Piozzi gave up her Welsh property to her husband's son, and spent most of the rest of her life at Bath and Clifton. When long past seventy she took a fancy to William Augustus Conway, the actor. She retained her vivacity to the last, celebrating her 80th birthday by a ball to six or seven hundred people at Bath. She died at Clifton on the 2nd of May 1821.

From 1776 to 1829, she kept a notebook which she called "the Diary." Her well-known poem of the "Three Warnings" is to be found in many popular collections. Letters to and from the late Samuel Johnson appeared in 1788: Observations and Reflections made in the course of a Journey, through France, Italy and Germany, in 1795; and in 1801 she published "Retrospections" or a review of the most striking and important events, characters, and situations... which the last eighteen years have presented to the view of mankind (1801). See Letters and Literary Remains of Mrs Piozzi (Thrale), edited with notes and an Introductory Account of her Life and Writings by A. Hayward (1861); Piozzianna; or Recollections of the late Mrs Piozzi by a Friend (1833), the anonymous (friend being Edward Maning (1772-1855)), and by B. Selvey, Mrs Thrale, afterwords Mrs Piozzi... (1891), and G. Birkbeck Hill, Johnsonian Miscellanies (1897). Also works noted in bibliography to Johnson, Samuel.

PIPE, a term used of a musical wind-instrument of tubular form, and hence of any cylindrical hollow tube. The original application of the term is to the musical instrument (see Pipe and Tambor below), and the source is to be found in Lat. piper, to chirp, of a bird. The general meaning of "pipe," in the sense of a tube for such purposes as carrying water, gas, sewage, &c., is treated under TUBE. Among specific uses of the word are those for the hollow stem of clay, wood or other material with a bowl at one end in which tobacco is smoked (see below); for the metal or wooden sound tubes in an organ (q.v.); and for various forms of cylindrical veins, hollows, channels, &c., in mining and geology. The Great Roll of the Exchequer was known as the "Pipe Roll"; this contained the various "pipes" or enrolled accounts of the sheriffs, &c., which were so called either from being set in a cylindrical case or as resembling a pipe in shape when rolled (see CORDS).

Tobacco Pipe.—The smoking of tobacco in pipes is a custom which prevailed in America for a period of unknown duration previous to the discovery of that continent by Columbus. The most ancient pipes of which remains exist have been found in mounds or tumuli called pipe mounds, principally in Ohio, Indiana, Illinois and Iowa. These mound pipes, which are carved in porphyry and other hard stones, are very uniform in type. The pipe, cut out of a single piece of stone, consists of a slightly convex platform or base, generally from 3 to 4 in. in length, and about an inch broad, with the bowl on the centre. A fine hole is pierced from one end of the platform to the bottom of the bowl, the opposite end being obviously for holding in the hand while the pipe is being smoked. In the commonest forms the bowl is a simple cylinder or urn (fig. 1), but in many cases remarkable artistic skill has been displayed in carving the bowls into miniature figures of birds, mammals, reptiles and human heads, often grotesque and fantastic, but always vigorously executed (fig. 2). These mound or platform pipes with carved human and animal forms are objects of the highest ethnographic interest and importance, being among the most characteristic remains of the ancient inhabitants of the Mississippi valley. The wide area over which they, as well as remains of baked clay pipes, are found throughout the American continent testifies to the universal prevalence of smoking in the pre-Columbian era. Many of the ancient clay pipes found in Mexico, &c., are elaborately moulded and ornamented, while others show considerable similarity to the early clay pipes of Europe. Among the North-American tribes the tobacco pipe occupies a position of peculiar symbolic significance in connection with the superstitious rites and usages of the race. The calumet, peace pipe or medicine pipe, is an object of the most profound veneration, entrusted to the care of a highly honoured official, and produced and smoked with much ceremony only on occasions of great importance and solemnity. It is remarkable that, whilst the most ancient American pipes had no separate stem, it is the stem only of the medicine pipe which is the object of veneration among the Indians, the bowl used being a matter of indifference. The favourite material for Indian pipe bowls is the famous red pipe stone (catlinite), a fine-grained easily-worked stone of a rich red colour of the Côteau des Prairies, west of the Big Stone Lake in S. Dakota. The quarries were formerly neutral ground among the warring Indian tribes, many sacred traditions being associated with the locality and its product.

It is disputed whether pipes for smoking were at all known in Europe previous to the discovery of America. That tobacco-smoking was unknown is certain; but pipes of iron, bronze and clay have been so frequently found associated with Roman remains and other antiquities as to lead many authorities to maintain that such pipes must have been anciently used for burning incense or for smoking aromatic herbs or hemp. Throughout Great Britain and Ireland small clay pipes are frequently dug up, in some instances associated with Roman relics. These are known amongst the people as elfin, fairy or Celtic pipes, and in some districts supernatural agencies have been called in to account for their existence. The elfin pipes have commonly flat broad heels in place of the sharp spur now found on clay pipes, and on that flat space the mark or initials of the maker is occasionally found. There is no reason to believe that these pipes are older than the 17th century. The introduction of the tobacco pipe into Europe is generally ascribed to Ralph Lane, first governor of Virginia, who in 1586 brought an Indian pipe to Sir Walter Raleigh, and taught that courtier how to use the implement. The pipe-makers of London became an incorporated body in 1619, and from England the other nations of Europe learned the art of making clay pipes.

The habit of smoking with pipes spread with incredible rapidity; and among the various peoples the pipe assumed special characteristics, and its modifications became the medium of conveying social, political and personal allusions, in many cases with no little artistic skill and humour. The pipe also became the object of much inventive ingenuity, and it varied as greatly in material as in form—wood, horn, bone, ivory, stone, precious and other metals, amber, glass, porcelain and, above all, clay and the materials employed in various forms. By degrees pipes of special form and material came to be associated with particular people, e.g., the elongated painted porcelain bowls and pendulous stem of the German peasant, the red clay bowl and long cherry wood stem of the Turk, and the very small metallic bowl and cane stem of the Japanese, &c. Among other kinds of pipe which have been popular at various times are the "corn-cob," where the bowl is made of the cob of maize or Indian corn, and the "calabash" with the bowl of a small gourd. The "churchwarden" is a clay pipe with a slender stem, some 16 or 20 in. long. The most luxurious and elaborate form of pipe is the Persian kaloud, of which there are various kinds. This consists of three parts: the bowl or bowl water bottle on a base, and the snake or long flexible tube ending in the mouthpiece. The tobacco, which must be previously prepared by steeping in water, is placed in the head and lighted with live charcoal, a wooden stem passes from its bottom down into the water which fills the base, and the tube is fitted to a stem which ends in the bottle above the water. Thus the smoke is cooled and washed before it reaches the smoker by passing through the water in

Fig. 1.—"Monitor" Pipe.

Fig. 2.—Heron Pipe.
PIECE AND TABOR—PIPER

the bottle, and by being drawn through the coil of tube frequently some yards in length. The bottles are in many cases made of carved and otherwise ornamented coco-nut shells, whence the apparatus is called narghile, from narg, a nut. Silver, gold, damascened steel and precious stones are freely used in the making and decoration of these pipes for wealthy smokers.

Pipe Manufacture.—The regular pipe-making industries divide into many branches, of which the more important are the clay pipe; meerschaum (real and artificial), and wooden bowl trades. Clay pipes are made in prodigious numbers by hand labour with an iron mould and a steel wire for forming the tube of the stem. Pipe-moulding is a very simple operation in pottery, and the work is performed by a spinning wheel. Various devices of machinery have been devised for automatic pipe-moulding; but the manual operations are so rapid and inexpensive that there is little margin for saving by the substitution of machinery. The pipes are very slightly fired so as to keep them soft and porous; and so cheaply made are they that the commoner kinds can be retailed at a profit for a farthing each. The principal early centres of the clay-pipe industry were at Broseley in Staffordshire, where the trade has been established since the early part of the 17th century, and at Amesbury in Wiltshire. The manufacture is still carried on at Broseley. Meerschaum pipes (see Meerschaum) are the luxury of the European smoker. The favourite wooden pipe generally known as a briar-wood or briar-root pipe is really made from the roots of the tree heath, Erica arborea (Fr., bruyère), principally obtained on the hills of the Marennes and taken thence to Lehogn. There the roots are shaped into blocks each suitable for a pipe, the cutting of the wood so as to avoid waste requiring considerable skill. These blocks are simmered in a vat for twelve hours, which gives them the much-appreciated yellowish-brown hue of a good briar-root. So prepared the blocks are exported for boring and finishing. Many devices have been invented for the purpose of preventing the nicotine liquor from reaching the smoker’s mouth or collecting in and fouling the pipe.

PIPE AND TABOR (Fr. galoubet; Ger. Schweigel or Stutentipspeck), a popular medieval combination of a small pipe or fipple and a small drum. These pipes consist of a cylindrical tube of narrow bore, pierced with three holes, two in front and one at the back, all very near the end of the pipe; and of a mouthpiece of the kind known as whistle, fipple or beak common to the flûtes à bec or recorder family. The compass of this instrument, with no more than three holes, exceeds two octaves in the hands of a good player, and is chromatic throughout. The fundamental notes of the open pipe and of the three holes cannot be produced; the scale consists, therefore, entirely of harmonics, the 2nd, 3rd and 4th of the series being easily obtained, and, by half stopping the holes, also the semitones which are required to complete the chromatic scale. The tabor being fastened to the performer’s left elbow, the hands remained free, the right beating the little drum with a stick to mark the rhythm, while the left held and fingered the pipe with thumb and first two fingers.

Mersenne mentions a wonderful virtuoso, John Price, who could rise to the twenty-second on the galoubet. Praetorius mentions and figures three sizes of the Stutentipfelh, the treble 20 in. long, the tenor 26 in. and the bass 30, the last being played by means of a crook about 23 in. long. A specimen of the bass in the museum of the Brussels Conservatoire has for its lowest note middle C. The pipe and tabor are said to be of Provençal origin; it is certain that they were most popular in France, England and the Netherlands, and they figure largely among the musical and social entertainments of the wealthier classes of those countries. (K. S.)

PIPE-FISHES (Syngnathidae), small fishes, which with the Sea-horses form a distinct family, Syngnathidae, of Lophobranchiate

narrow and small mouth which opens upwards and is toothless. The body and tail are long and thin, snake-like, encased in hard integuments which are divided into regularly arranged segments. The dorsal fin is always present, and is the principal (in some species, the only) organ of locomotion. The ventral fins are as constantly absent, and the other fins may or may not be developed. The gill-openings are extremely small and placed near the upper posterior angle of the gill-cover. Most of the pipe-fishes are marine, only a few being freshwater. Pipe-fishes are abundant on such coasts of the tropical and temperate zones as offer by their vegetation shelter to these defenceless creatures. They are very bad swimmers, slowly moving through the water by means of the rapid undulatory movement of the dorsal fin. Their tail, even when provided with a caudal fin, is of no use in swimming, and not prehensile as in sea-horses. Specimens, therefore, are not rarely found at a great distance from land, having been resistlessly carried by currents into the open ocean; one species, Syngnathus pelagicus, has an extraordinarily wide range over the tropical seas, and is one of the common fishes inhabiting the vegetation of the Sargasso Sea. The colour of these fishes often changes with the sea-weeds among which they may be found, passing from brown to green or even brick-red. In pipe-fishes the male is provided with a pouch in some species on the abdomen, in others on the lower side of the tail—in which the ova are lodged during their development. This marsupial pouch is formed by a fold of the skin developed from each side of the trunk or tail, the free margins of the fold being firmly united in the median line throughout the period during which the eggs are being hatched. When the young are hatched the folds separate, leaving a wide slit, by which the young gradually escape when quite able to take care of themselves. Nearly a hundred different species of pipe-fishes are known, of which Siphonostoma typhle, Syngnathus acus (the Great Pipe-fish up to 18 in. in length), Nerophis aquaeus (Ocean Pipe-fish), Nerophis opilion (Straightnosed Pipe-fish), and Nerophis turbirciformis (Little Pipe-fish) are British species. The last three are destitute of a caudal fin.

PIPER, CARL, Count (1647-1716), Swedish statesman, was born at Stockholm on the 29th of July 1647. He entered the foreign office after completing his academic course at Upsala, accompanied Benedict Oxenstierna on his embassy to Russia in 1673, and attracted the attention of Charles XI. during the Scanian War by his extraordinary energy and ability. In 1679 he was appointed secretary to the board of trade and ennobled. In 1680 he was made one of the secretaries of state, and Charles XI. recommended him on his deathbed to his son and successor, Charles XII. Piper became the most confidential of the new sovereign’s ministers. In 1693 he was made a senator and set over domestic affairs while still retaining his state-secretaryship. In 1698 he was created a count, in 1702 appointed chancellor of Upsala University, and during the first half of the Great Northern War, as the chief of Charles’s perambulating chancellery, he was practically prime minister. It was his misfortune, however, to be obliged to support a system which was not his

Fig. 1.—Syngnathus acus, Male, with sub-caudal pouch.

Thoracosnet. The name is derived from the peculiar form of their snout, which is produced into a more or less long tube, ending in a
own. He belonged to the school of Benedict Oxenstierna and was therefore an avowed advocate of a pacific policy. He protested in vain against nearly all the military ventures of Charles XII., e.g. the War of Deposition against Augustus of Saxony and Poland, the invasion of Saxony, the raid into the Ukraine. Again and again he insisted that the pacific overtures of Peter the Great should at least be fairly considered, but his master was always inexorable. Piper's career came to an end at Poltava (1709), where he was among the prisoners. The last years of his life were spent in exile in Russia. He died at Schlüsselburg on the 29th of May 1716.

See W. L. Svedelius, Count Carl Piper (Stockholm, 1869) (Eng. N. B).

PIPERAZIN—PIPPIN

PIPERAZIN, a substance formed by the action of sodium glycol on ethylene-diamine hydrochloride, consisting of small alkaline deliquescent crystals with a saline taste and soluble in water. It was originally introduced into medicine as a solvent for uric acid. When taken into the body the drug is partly oxidized and partly eliminated unchanged. Outside the body piperazin has a remarkable power of dissolving uric acid and producing a soluble urate, but in clinical experience it has not proved equally successful. Lycetol, lysidine and sidonal are bodies having similar action.

PIPERINE, C19H19NO, an alkaloid found in the fruits of Piper nigrum and P. longum. It forms white prisms, which melt at 125°-219°. It is almost insoluble in water, but readily soluble in alcohol and ether. It is a very weak base, salts being only formed with mineral acids, and these are dissociated by water. Alcoholic potash decomposes it into piperidine, C12H18N, and piperic acid, C12H17O. The constitution of piperic acid was elucidated by R. Fittig and his pupils (Ann., vol. 152, 150, 168, 216, 227) and shown to be (1). Piperine consequently is (2).

\[
\begin{align*}
\text{(1)} & \quad \text{CH} - \text{CH} - \text{CH} - \text{COOH} \\
\text{(2)} & \quad \text{CH} - \text{CH} - \text{CH} - \text{CO-N(CH}_3\text{)}_2
\end{align*}
\]

Oxidation with potassium permanganate converts piperine into piperonal, C18H20O, and piperonylic acid, C12H17O. The latter when heated with hydrochloric acid to 170°, or water to 200°, separates carvone with the formation of pteracetic acid, 1,2-dioxy-3-benzoic acid, C12H16(OH)2COOH. Conversely, by heating pteracetic acid with potash and methylene iodide, piperonylic acid was regained. These results show that piperonylic acid resembles methylene ether of pteracetic acid, Pteronal (q.v.) is the corresponding aldehyde. Picroic acid differs from piperonylic acid by the group CH2, and it was apparent that these carbon atoms must be attached to the carbon atom which appears in the carboxyl group of piperonylic acid, for if they were directly attached to the benzene ring polyarboxylic acids would result in oxidation. The above formula for piperic acid was confirmed by its synthesis by A. Ladenburg and M. Schultz (Ber., 1894, 27, p. 2958) from piperonyl acrolein (the condensation product of piperonal and acetaldehyde) and acetic acid. The synthesis of piperine follows from the interaction of piperyl chlorides (formed from piperonic acid and phosphorus pentachloride) and piperidine (L. Rubekimmer, Ber., 1882, 15, 1390).

PIPERINO (anc. Princrum), a town of the province of Rome, Italy, 61 m. S.E. of Rome by rail. Pop. (1901), 6756. The medieval town was founded in the 10th century (7) on a hill 490 ft. above sea-level, by refugees from the Roman town of Prinvernium, lower down (115 ft. above sea-level) on the highroad, 1 1/2 m. to the north, at the mouth of a low pass leading through the Volscanian mountains to the valley of the Sacco. Here are remains of an arch crossing the road and other ruins (mostly buried) of the Roman period; but the remains above ground are largely medieval. It is improbable, however, that the ancient Volscan town should have occupied so easily accessible a site; it is not unlikely that it stood on the site occupied by the medieval and modern town, but there is no proof of this. Prinvernium was a Volscan town, and took up arms against Rome after the foundation of a Latin colony at Setia in 382 B.C. It was finally captured in 320 B.C. and eleven years later the tribus Oufentia was founded, taking its name from the river Ouifens (mod. Uffente) in the territory of Prinvernium. Little is known of it subsequently. The medieval town has a picturesque piazza, with a Gothic cathedral (1283), which preserves a fine porch, though the interior was modernized in 1782; a Gothic palazzo pubblico; and other Gothic churches exist in the town. Polygonal terrace walls of the Roman or pre-Roman period exist at various places in the vicinity (G. B. Giovenale and L. Mariani in Notizie degli Scavi, 1890, 88).

(P. A.)

PIPERONAL (heliotropine, protocatechuic aldehyde methylene ether), C19H19O, an aromatic aldehyde. It is prepared by oxidizing piperic acid with potassium permanganate (R. Fittig, Ann., 1869, 152, p. 35); by condensing methylene iodide with protocatechuic aldehyde (R. Wegscheider, Monats., 1893, 14, p. 388); or by oxidizing isosafrol with chromic acid. It forms long colourless crystals which melt at 130° C. and boil at 262° C. It has an agreeable smell, resembling that of heliotrope, and is much used in perfumery. It is only slightly soluble in cold water, but is readily soluble in alcohol and in ether. When heated with dilute hydrochloric acid to 200° C. it yields protocatechuic aldehyde, C12H16O, and carbon. It readily combines with sodium bisulphite and with various bases (ammonia, aniline, methylamine, &c.).

PIPIP (cognate with the Lat. Pilip; see PIGEON), the name applied by ornithologists to a group of birds having a great resemblance both in habits and appearance to the larks (q.v.). Fittig divided them, however, into larks in several important characters; and, having been first separated to form the genus Anthus, which has since been much broken up, are now generally associated with the waggots (q.v.) in the Passerine family Motacillidae. Pipits, of which over fifty species have been described, occur in almost all parts of the world, but in North America are represented by but two species—Neocorys spraguei, the prairie-lark of the north-western plains, and Anthus ludovicianus, the American titlark, which last is very nearly allied to the so-called water-pipit of Europe, A. spinola. To most English readers the best known species of pipit is the titlark or meadow-pipit, A. pratensis, a bird too common to need description, and abundant on pastures, moors, and uncultivated districts generally; but in some localities the tree-pipit, A. trivialis, or A. arbores of some authors, takes its place, and where it does so it usually attracts attention by its loud song, which is not unlike that of a canary, but delivered (as appears to be the habit of all the pipits) on the wing and during a short circuitous flight. Another species, the rock-lark, A. obesus, scarcely ever leaves the sea-coast and is found almost all round the British Islands. The South-African genus Macronyx, remarkable for the extreme length of its hind claw, is generally placed among the pipits, but differs from all the rest in its brighter coloration, which has a curious resemblance to the American genus Stereola (see ICERICAN), though the bird is certainly not allied thereto.

(A. N.)

PIPPIN, or PEPIN, the name of three members of the Carolingian family.

PIPPIN I. (d. 640), incorrectly called Pippin of Landen, was mayor of the palace to the youthful Dagobert I., whom Clotaire II. had placed over the kingdom of Austrasia. He was disgraced when Dagobert became sole king in 639, and had to seek refuge in Aquitaine. Returning at Dagobert's death (639), he governed Austrasia in Sigebert's name, but died in the following year.

PIPPIN II. (d. 714), incorrectly called Pippin of Herstal, was son of Adalgisius (son of Arnulf, bishop of Metz) by a daughter of Pippin I., called in later documents Begga. Towards 678 he placed himself at the head of the great nobles in Austrasia to combat Ebroin, the mayor of the palace, and Neustria. After some reverses he gained a great victory after Ebroin's death at the battle of Tertry, not far from St Quentin. This victory made Pippin almost entire master of Gaul. He appointed one of his sons mayor of the palace of Neustria, reserving for another of his sons the mayoralty of Austrasia. He made war
on the Frisians and defeated their duke Radbod; and part of this people became converts to Christianity. He also defeated Willari, the duke of the Alamanni, and subdued his country. The Bavarians, too, recognized the Frankish suzerainty. The plans he had formed for reforming the church and convoking councils were interrupted by his death, which took place on the 16th of December 714.

Pippin III. (d. 768), the Short,1 was son of Charles Martel. Before his death in 741 Charles Martel had divided the Frankish kingdom between his two sons, Carloman and Pippin, giving Carloman the eastern part and Pippin the western. Since 737 there had been no king in the Frankish realm; in the diploma the two brothers bear the title of magistri palatii, while the chroniclers call them simply principes. In 743, however, the mayors decided to appoint a king in the person of Childeric III., who was apparently connected with the Merovingian family. But Childeric was a mere figure-head, and had no power. The two brothers presided over the tribunals, convoked the councils at which the Frankish Church was reformed, assembled the host and made war, jointly defeating and subduing Duke Hunald of Aquitaine. In 747 Carloman unexpectedly abdicated, became a monk, and retired to a monastery near Rome, subsequently founding on Mt Soracte the monastery of St. Sabina. From the time of the abdication Pippin was sole master; and in 751, after consulting Pope Zacharias, he took the title of king and removed the feeble Childeric to a monastery. He then got himself crowned by St Boniface, a ceremony which was new to France and which gave the sovereign immense prestige; henceforth the king of the Franks called himself Gratia Dei rex Francorum. Pippin's reign is marked by many important events. He received in France a personal visit from Pope Stephen II., who conferred on him the title of Patriarch of the Romans and reconquered him. In return for these honours Pippin, at the appeal of the pope, made two expeditions into Italy, in 754 and 756; and he became the very creative of the papal state by conferring on the pope, the exarchate of Ravenna, which he had wrested from Aistulf, the king of the Lombards. Pippin took Septimania from the Arabs, and after a stubborn war of nearly eight years' duration (760-68) succeeded in taking Aquitaine from its duke, Waifer. He also intervened in Germany, where he forced the duke of Bavaria, Tassilo, to become his vassal. In 763, however, Tassilo abandoned Pippin during an expedition against Aquitaine. Pippin made several expeditions against the Saxons, but failed to subdue them. He entered into relations with the Eastern Empire, exchanging ambassadors with the emperor Constantine Copronymus. During Pippin's reign Frankish institutions were subjected to some modification. The Frankish assemblies, previously held in the month of March (champs de mar), but under Pippin deferred to May (champs de mai), came to be more numerous, and served the king of the Franks as a means of receiving the gifts of his subjects and of promulgating his capitations. At the head of the administration was placed the archchaplain, and an ecclesiastical chancellor was substituted for the ancient referendarius. Ecclesiastical reform was continued under Pippin, Bishop Chrodegangs of Metz uniting the clergy of Metz in a common life and creating canons (see Canon). Pippin died on the 24th of September 768 at St Denis, leaving two sons, Charles (Charlemagne) and Carloman.

Oelsner, Jahrbücher des frankischen Reiches unter König Pippin (Leipzig, 1893); J. F. Bührer and E. Mühlbacher, Regesta des Karolingerreiches unter dem Karolingern (ed. 1869 and 1876); and E. Mühlbacher, Deutsche Geschichte unter den Karolingern (Stuttgart, 1896).

PIPRĀWA, a village on the Birdpur estate in the Basti district, United Provinces, India. It lies on the Uska-Nepal road at mile 197-75; and about half a mile south of the boundary pillar numbered 44 on the frontier line between British and Nepalese territory. The village is celebrated as the site of the following discovery:—

In 1866 interest having been aroused by the discovery, only twelve miles away, of the Buddha's birthplace (see LUMBI), William Peppé, then resident manager of the Birdpur estate, opened a ruined tope or burial mound situated at Piprawa, but nothing of importance was found. In January 1867 he carried the work of excavation farther. A well, 10 ft. sq., was dug down to the centre of the mound. After digging through 18 ft. of solid brickwork set in clay a massive stone coffin was found lying due magnetic north and south. Its dimensions were, in. by 2 ft. 8 in. and 2 ft. 2 in. high. The stone lid of the coffin was split into four pieces, but the coffin remained perfectly closed, so accurately was the lid fitted into flanges on the sides of the box. The pieces were thus firmly held in their place, and the contents of the coffin were found intact. These consisted of five vessels, two vases, a bowl and a casket being made of stelitite, and the fifth, also a bowl, of crystal. All these vessels are beautifully worked, the crystal bowl especially, with its fish-shaped cover handle, being as a work of art of high merit. The coffin is of fine hard sandstone of superior quality, and has been hollowed out, at the cost of vast labour and expense, from a solid block of rock. Peppé calculates its weight, lid included, at 1,525 lb. It is only the great solidity of this coffin which has preserved the contents. A cover of one of the vases was found detached and lying on the bottom of the stone coffin. As this cover fits very well it must have required a quite violent shock to remove it. This was almost certainly the shock of an earthquake, and the same shock probably caused the split in the stone lid of the coffin itself.

The vessels contained a dark dust, apparently disintegrated ashes, small pieces of bone, and a number of small pieces of jewelry in gold, silver, white and red cornelian, amethyst, topaz, garnet, coral and crystal. Most of these are perforated for mounting on threads or wires, and had been, no doubt, originally connected together to form one or more of the elaborate girdles, necklaces and breast ornaments then worn by the women. On the bottom of the stone box there was similar dust, pieces of bone and jewelry, and also remains of what had been vessels of wood. The knob forming the handle of one of these wooden receptacles was still distinguishable. The total quantity of scraps of bone may have amounted to a wineglassful.

An inscription ran round one of the stelitite vases just below the lid. The words mean: This shrine for ashes of the Buddha, the Exalted One, is the pious work of the Sakhyas, his brethren, associated with their sisters, and their children, and their wives. The thirteen words, in a local dialect of Pali, are written in very ancient characters and are the oldest inscription yet discovered in India. Twelve out of the thirteen are well-known words, the interpretation of which is not open to doubt. One word, rendered above by "pious work," has not been found elsewhere, and its derivation is open to discussion. The explanation here adopted as most probable was put forward by Professor Fischel of Berlin. The phrase "pious work" probably had a precise technical connotation like the English "benefaction." The monument must have been of imposing appearance. The diameter (on the ground level) of the dome is 116 ft. For 8 ft. from the summit of the ruin it was not possible to trace the outline. At that point the outer wall, if one may so call it, of the solid dome could be traced, and had a diameter of 68 ft. The dome, therefore, sloped inwards 1 ft. for every 3 ft. in height, in other words, it was, like all the most ancient of these artificial burial domes in India, a shallow dome, and cannot have been more than about 35 ft. high exclusive of the ornament or "tee" on the summit. We have in bas-reliefs of the 3rd century representations of what these ornaments were like—small urns. An illustration from a photograph is given in Rhys Davids' Buddhists of India, p. 131. For figures of the jewel found see the plate in Mr Peppé's article reproduced in Rhys Davids' Buddhists India, p. 89, for the jewelry of the time, ibid., pp. 90, 91, 129.

1 See illustration ibid., p. 129.
2 Zeitschrift der deutschen morgenländischen Gesellschaft, lxi. 157.
PIQUA—PIQUET

square erections, like a shrine or small temple, surmounted by a canopy called from its shape a T. They were then more than a third of the height of the dome itself. The total height of this Sâkiya tope will therefore have been approximately a little under 50 ft. It was probably surrounded by a carved wooden railing, but this has long since disappeared.

All such monuments hitherto discovered in India were put in honour of some religious teacher, not in memory of royal persons, generous benefactors, politicians, or soldiers or private persons, however distinguished. And we need have no hesitation in accepting this as a monument put up over a portion of the ashes from the funeral pyre of Gotama the Buddha. The account of the death and cremation of the Buddha, preserved in the Buddhist canon, states that one-eighth of the portion of the ashes was presented to the Sâkyan clan, and that they built a śākya, or memorial mound, over it.1

Mr Peppe presented the cofers and vases with specimens of the jewelry to the museum at Calcutta where they still are. He also gave specimens of the trinkets to the Asiatic Society in London.

Peppe's original article is in the Journal of the Royal Asiatic Society for 1898, pp. 573 sqq. Comments upon it, one or two of them sceptical, are in the same journal 1898, pp. 579, 588, 587, 586; 1899, pp. 398; 1906, pp. 109, 113. See also A. Barth, Comptes rendus de l'académie des inscriptions (1898), xxvi., 147, 233; Sylvain Levy, Journal des savants (1905) pp. 540 sqq.; and R. Pachol and Rhys Davids as quoted above. (T. W. A. R. C.)

PIQUA, a city of Miami county, Ohio, U.S.A., on the Miami River and the Miami & Erie Canal, 73 m. W. by N. of Columbus. Pop. (1890), 9000; (1900), 12,172, of whom 901 were foreign-born and 487 were negroes; (1910 census), 13,888. It is served by the Pittsburg, Cincinnati, Chicago & St. Louis, and the Cincinnati, Hamilton & Dayton railways, and by inter-urban electric lines to Lima, Dayton and Covington. It has a park, a public library and a public hospital. There are reservoirs of blue limestone in the vicinity. The city has various manufactures, the factory products being valued in 1905 at $4,635,706. The municipality owns and operates its waterworks. On or near the site of Piqua was one of the principal villages of the Chillicothe division of the Shawnee tribe; the village also was called Chillicothe. It was destroyed by George Rogers Clark in 1782. A town was laid out here in 1809 under the name of Washington, and the present name, that of another division of the Shawnee tribe, was substituted in 1823. Piqua was chartered as a city in 1846. During the French and Indian War, in 1763, a battle was fought in this vicinity chiefly between the Miamiis, Wyandots, Ottawa and other Indian allies of the French, and the Delawares, Shawnees, Cherokees, Catawbas and other Indian allies of the English, the English allies making an unsuccessful attempt to drive the French allies from their fortified position, Fort Piqua.

Sec Henry Howe, Historical Collections of Ohio (Columbus, 1891).

PIQUET, a game at cards, probably a development of rofia, a game mentioned by Berni in 1526; la rofie (included in Rabelais's list, c. 1530) may be regarded as the same game. The point at piquet was anciently called rofie. The Spanish name of the game was cienos (centum, a hundred). Piquet was played in England under the name of cent or sart, probably as early as 1530 (contemporaneously with the marriage of Mary to Leopold of Spain). About the middle of the 17th century (shortly after the marriage of Charles L to Henrietta Maria of France) the name cent was dropped in England, and the French equivalent, piquet, adopted. It is played by two persons, with a pack of thirty-two cards—the sixes, fives, fours, threes and twos being thrown out from a complete pack. At one time the partie was the best of five games of a hundred up (a player not obtaining fifty losing a double game). But now the partie is generally determined in six hands, the player making the largest aggregate score being the winner. The number of points won is the difference between the two scores, with a hundred added for the game. If, however, the loser fails to make a hundred in six hands, the number of points won is the sum of the two scores, with a hundred for the game. Piquet played in this way is called Rubicon Piquet.

The dealer deals twelve cards to his adversary and twelve to himself, two at a time, or three at a time. He then places the two hands (or stock) of cards face downward on the table, the top five being for the elder hand (non-dealer) to take from first in exchange for his own. The players now look at their hands (or carte blanche) and if this has been declared, if there is one, put out (without showing them) each as many cards as seem best, in order to improve their hands, and take in an equivalent number from the stock. Each player must discard at least three cards. The elder hand begins. Whatever the elder hand lays to, he must state how many he leaves. He is entitled to look at the cards he leaves, replacing them face downwards on the top of the stock. The younger hand then takes the exchange from the stock of the order of the stock. If the elder hand leaves any of the five, the younger may exchange as many as remain in the stock, discarding an equal number. If the younger hand leaves any cards, he announces the number left. He may look at the cards he leaves. If he looks at them he must show them to the elder hand, after the elder has named the suit he will lead first, or has led a card.

The younger hand elects not to look at the cards left the elder cannot see them. The younger hand must make his election before he plays to the card first led, or, if so required, after the dealer has named the suit he will lead first. Each player may examine his cards at any time during the hand; but he must keep it separate from his other cards.

The elder hand next makes a declaration of what he has in his hands. The "point" must be called first or the right to call it is lost. It is scored by the player who announces the suit of greatest strength, valued thus: ace 11; court cards, 10 each; other cards, the number of pips on each. Thus if the elder hand's best suit is ace, king, nine, eight, he calls "five cards." If the younger hand has no suit of five cards, he says "good." The elder hand then says "in spades," or whatever the suit may be, or shows his point again. If the younger hand has hands of five of his own he must say "good." If the elder hand has a suit of five cards, he says "not good." If the younger hand has also five cards, he says "equal" or "what do they make?" when the elder calls "forty-eight" (or "making eight," short for forty-eight), the younger must say whether the number of his cards is an equal number of cards. If the younger hand's five cards make less than forty-eight he says "good"; if exactly forty-eight he says "equal"; if more than forty-eight he says "not good." The younger player whose point is good reckons one for each card of it, if the points are equal neither player scores for point.

"Sequences" are usually called next, the elder hand stating whether his sequence is "good," the younger answering whether his "or not good," as in the case of the point. Any three or more consecutive cards of the same suit held in hand constitute a sequence. The order of the cards is as follows: ace (highest), king, queen, jack, nine, eight, seven, six, five, four, three, two, one. A sequence of three cards is called a "tierce"; of four, a "quart"; of five, a "quint"; of six, a "sexième"; of seven, a "septième"; of eight, a "huitième." A tierce of ace, king, queen is called a "tierce major"; a tierce of ace, king, nine, eight is called a "tierce minor." The remaining two other intermediate sequences according to the card which heads them); a tierce of nine, eight, seven is called a "tierce minor." Sequences of four or more cards follow the same nomenclature; e.g. ace, king, queen, knave is a quart major; knave, ten, nine, eight, a quart to a knave; and so on. A sequence of a greater number of cards is good against a sequence of a smaller number; thus, a quart minor is good against a tierce major. As between sequences containing the same number of cards, the one headed by the highest card is good; thus, a quart to a king is good against a quart to a knave. Only identical sequences can be equal. The three "quart" sequences are: three (including the next ten and in addition for quints or higher sequences. Thus a tierce counts three; a quart, four; a quint, fifteen; a sixième, sixteen; and so on. If the elder hand's sequence is good, he names the suit, or shows his point again. The younger, who is still holding his cards, (or carte blanche) is entitled to declare that the suit is "wrong," and the order of the stocks to be reversed. The elder hand's sequence is good, all lower sequences can be reckoned, notwithstanding that the adversary has a sequence of intermediate value. For example, A has a quart to a queen (good), and a tierce minor. He declares his sequence is wrong, the order of the stocks is reversed, and the younger player, who has a tierce to a queen, is good, but the elder player仍有序列为正确，因此他可以重新断定他的手牌为正确。B's quart counts nothing. If the highest sequence is equal, neither player scores anything for sequence, even though one player may hold the "same" sequence. "Trios" and "quartes" are the next cards. "Quartes" are composed of four aces, four kings, four queens, four knaves, or four aces, in order of value; "quartes" of three of any of these. A sequence of three is "good," a quart is "equal," a quint is "wrong," that is, the one that is good establishes any smaller quartes or trios in his hand.

When the elder hand has done calling he leads a card. Before

1Translated in Rhys Davids' Buddhist Suttas (Oxford, 1881).
PIRAM—PIRATE AND PIRACY

playing to this card, the younger hand recollects all that he has said, stating of what cards his claims are composed, or showing the cards claimed for. The elder hand leads any card he pleases; the younger plays to it. The younger hand must follow suit if able; otherwise he may play any card he thinks fit. If he has no card of the suit led, whether he wins the trick or not. If the second player wins the trick he also counts one. The winner of the last trick counts an additional one for the last card. The tricks are left face upwards in front of the player who wins them. They may be examined by either payer.

If each player wins six tricks the cards are "divided," and there is a distribution of the cards. For the six tricks he wins the cards, and adds ten to his score. If one player wins every trick, he wins a capot, and scores forty for the cards, instead of ten.

During the play of the hand, a player is entitled to be informed as to any cards his adversary holds which he has reckoned as good, or has declared to be equal. A player may require his adversary to state his cards, for which the adversary then shows his cards of a six, nine, or a five, as the case may be, declared as a quint, is asked how many he has left, he need only reply "Two."

During the progress of the hand each player repeats aloud the amount of his score for the square in which he is dealt for, for which the adversary then shows his cards of a six, nine, or a five, as the case may be, declared as a quint, is asked how many he has left, he need only reply "Two."

The hand then proceeds thus. A (calling his point) "five cards."

B says, "I have five that do the same."

A "forty-nine," or "making nine." B "good."

A (counting his point) "five" and, counting the sequence, which is good, "a quart major, nine. Three knaves, ten." B "not good."

A then says, "and says four, fourteen, and three queens, seventeen" (plays the ten of hearts).

A (leads the remaining hearts and says) "eleven, twelve, thirteen, fourteen." B (plays seven, ten, knave, queen of diamonds, and repeating his score says) "seventeen."

A has now five tricks, and in order to win the cards should lead any card but a high spade. He leads king of diamonds, and says, "of." B (with ace and says) "at the" (and then hands the winning cards, saying) "nineteen, twenty, twenty-one, twenty-two."

A (keeps ace, knave of clubs, and repeating his score says) "fifteen." B (of spades and says) "twenty-three." B (with ace and says) "sixteen" (and leads knave, saying) "eighteen" (and adding ten for the cards) "twenty-eight."

A then writes on his scoring card 28; B writes on his 23; B then says, "and adds the game" and hands the card. Three scores (omitted in order to simplify the description of the game) have yet to be mentioned.

The lower player has no king, queen or knave in the hand dealt him, he holds carte blanche, for which his score ten. As soon as a player discovers he has a carte blanche, he must tell his adversary; this he usually does by saying, "discard for carte blanche."

The adverse discard is then made (as explained under discarding), after which the carte blanche is shown by dealing the cards, face upwards on the table; they are then taken back into the hand.

Pause.—If the elder hand scores, in hand and play, thirty or more, before the younger hand counts anything in that deal, he gains a pique, for which he scores thirty.

Pique.—If a player scores in hand alone thirty or more before his adversary scores twenty or more, he gains a pique, for which he adds sixty to his score. Equalities do not prevent picques or repiques. A player who has an equal point or sequence scores nothing for it. Therefore if, notwithstanding the equality, a player makes thirty, in hand and play, or in hand, by scores which reckon in order before anything his adversary can count, he gains a pique or a repique.

In the order in which the scores accrue is of importance. For the sake of convenience, the elder hand finishes his reckoning before the younger begins. The scores, however, whether made by the elder or younger hand are recordable in the following order: (1) cards; (2) picques and repiques; (3) scores (equalities); (4) Fouquet's quadragesimo minor (5) points made in play; (6) the cards. This will often affect a pique or repique. Thus, a pique can only be made by the elder hand, as the one he recollects in play when he leads his first card counts before points subsequently made in play by the younger hand. The younger, therefore, cannot make thirty in hand and play before the elder scores one. But the one reckoned by the elder hand when he leads his first card does not prevent his being repiqued, because scores made in hand have precedence of points made in play. The elder leads his first card and counts for it before the younger reckons, simply as a convenient way of stating what has nothing to do with the play at all. By this, say A has a quint (good), a tierce, and a quatorze (good). He scores sixty points. If the opponent then wins the trick, he has repiqued A, which counts as good, because the younger hand's point is recordable after order has been gained, and the repique loses precedence of all other scores, saves picques and repiques. It also counts towards picques and repiques. A capot does not count towards a pique, as the capot is not made in play. It is added after the play of the hand is over. A player who reckons nothing that hand as a penalty is not piqued or repiqued if he holds any cards which, but for the penalty, would have reckoned before his adversary could reach it.

PIRAM, or PERIM, an island in the Gulf of Cambay, forming part of Ahmadabad district, Bombay. Formerly notorious as the stronghold of a pirate chieftain, it has attained fame among palaeontologists for the large quantity of fossil remains discovered here in 1836, similar to the better-known Siwalik faunas.

PIRANESI, GIOVANNI BATTISTA, Italian engraver of ancient architectural subjects, was born in the earlier half of the 18th century, and studied his art at Rome. The great remains of that city kindled his enthusiasm and demanded portrayal. His hand faithfully imitated the actual remains of a fabric; his invention, catching the design of the original architect, supplied the parts that were wanting; his skill introduced groups of vases, altars, tombs; and his broad and scientific distribution of light and shade completed the picture, and threw a striking effect over the whole. One engraving after another was executed with much brilliancy; and, as the work went on, the zeal of the engraver waxed stronger. In course of time it was found necessary to call in the aid of all his children and of several pupils. He did not, in fact, slacken in his exertions till his death in 1778.

The plates of Piranesi, in which the severity of burin work is largely supplemented by the freer lines of the etching-needle, were collected and preserved by his son and coadjutor Francesco. They were published, to the number of about 2000, in 29 vols. fol. (Paris, 1835-1837).

PIRANO, a seaport of Austria, in Istria, 22 m. S.W. of Trieste by rail. Pop. (1900), 13,330, mostly Italians. In addition to viticulture and the cultivation of the olive, its principal resources are ship-building and fishing. In the neighbourhood are the most extensive works in Istria for the extraction of salt from the sea-water, which produce about 50,000 tons of salt annually. Pirano is celebrated for the victory of the Venetians over the fleet of the emperor Frederick Barbarossa in 1177. It passed under the dominion of Venice in 1253 and became definitely incorporated with Austria, together with the other possessions of Venice in the Istrian Peninsula, in 1813.

PIRATE AND PIRACY. Sir Edward Coke (Instit. iii. 113) describes a pirate (Lat. pirata, from Gr. πειράτης, Πειρατής, to attempt or attack), as hostis humani generis, and as a robber upon the sea. Sir J. Fitzjames Stephen in his Digest of Criminal Law defined piracy as follows: "Taking a ship on the High Seas or within the jurisdiction of the Lord High Admiral from the possession or control of those who are lawfully entitled to it and carrying away the ship itself or any of its goods, tackle, apparel or furniture under circumstances which would have amounted to robbery if the act had been done within the body of an English county." (cf. A. G. for Hong-Kong v. Kwok-a-Sing, 1902; P. C. R. 547.) However, a pirate, that is any particular state but against all mankind, may be punished in the competent court of any country where the offender may be found or into which he may be carried. But, whilst the practice of nations gives to every one the right to pursue and exterminate pirates without any previous declaration of war (pirates holding no commission or delegated authority from any sovereign or state), it is not allowed to kill them without trial except in battle. Those who surrender or are taken prisoners
must be brought before the proper tribunal and dealt with according to law.

Piracy has dealt with in a large number of English statutes, from 1536 down to the Territorial Waters Jurisdiction Act 1878 (44 & 45 Vic., c. 73), which provided for the maintenance of the existing jurisdiction for the trial of "any act of piracy as defined by the law of nations."

During the Spanish-American War the Spanish government issued (1898) a decree declaring that "captains, masters and officers of vessels, which, as well as two-thirds of their crew, are not American, captured while committing acts of war against Spain, even if they are provided with letters of marque issued by the United States" would be regarded and judged as pirates. This was not in accordance with the international practice on the subject. A public ship or one which is entitled to fly the flag of a belligerent and navigates under the cover of state papers, by the very sense of the term, is not a pirate. Again, during the Russo-Japanese War, the word "piracy" was freely applied in British newspapers to the seizure of the "Malacca" and other vessels held up by the "Peterburg" and "Smolensk," two cruisers belonging to the Russian Black Sea volunteer fleet, which in July 1904 passed as merchantmen through the Bosporus and Dardanelles and were transformed to their real character on the open sea. The application of the term in this case was equally inaccurate.

The conversion of merchant into war ships was one of the subjects dealt with by the second Hague Conference (1907), but it was agreed that "the question of the place where such conversion is effected remains outside the scope of the agreement."

Piracy is essentially a crime under international law, and although any state may apply its penalties to its own subjects by analogy, as was done by Great Britain and the United States in connexion with the repression of the slave trade, they cannot be lawfully applied to subjects of other states. (T. B.)

Historical Sketch.—It has at all times been more difficult to enforce good order on the sea than on the land; or perhaps we ought to say that the establishment of law and order on the sea has in all ages of the world's history followed, but has not accompanied, and has still less preceded, the creation of a good police on the land. The sea robber, or pirate, cannot make a profit from any part of his booty except the food which he consumes, or the vessels which he may use, unless he can find a market. But so long as he is sure that he will somewhere meet a purchaser for the goods he has taken by violence, he has every encouragement to pursue his trade. Therefore from the times described in the Odyssey, down to the days when Sir Henry Keppel sailed in H.M.S. "Dido" to suppress the pirates of Borneo, and when Rajah Brooke of Sarawak co-operated with him on land, we find that the prevalence of piracy and the suppression of it have been closely dependent on the efforts made to rout it out from its lurking-places on the coast, and the degree of success achieved.

Very different types of men have been named pirates. They have in fact been so unlike that to class them all together would be in the last degree unjust. The Greek in the youth of the world, and the Malay of Borneo in the 19th century, knew of no rule of morals which should restrain them from treating all who lay outside the limits of their city or their tribe as enemies, to be traded with when strong and plundered when weak. They might be patriotic, and law-abiding men towards the only authority they recognized. Their piracy was a form of war, not without close moral analogies to the seizure of Silesia by Frederick the Great, the attempted seizure of Spain by Napoleon. Indeed the story of this latter venture, with its deceitful preliminary success and its final disaster, may fairly be compared with the fall of Ulysses and his companions on the Cicones, as told in the ninth book of the Odyssey. Yet it would be highly uncritical to class Ulysses or Napoleon with Captain Avery, or Captain Kidd, or Bartholomew Roberts. We are not here concerned with the legal aspects of piracy, but with the true character of the persons to whom the name pirate is applied at various times. The term was applied by the Romans to the adventurers against whom Pompey was commissioned to act by the Gabinian Law, by the English of the 9th and 10th centuries to the Vikings, and by the Spaniards to the English, French and Dutch who were found sailing beyond the line. Sufferers by naval commerce-destroyers call it a piratical warfare.” But the pirates of the Roman Republic were no mere “gang of robbers.” They were the victims of a time of conquest and “general overture” —the ruined men of all nations, the hunted refugees of all vanquished parties, everyone that was wretched and daring—and where there was not misery and violence in this unhappy age? It was no longer a gang of robbers who had flocked together, but a compact soldier state, in which the freemasonry of exile and of crime took the place of nationality, and within which crime redeemed itself, as it so often does in its own eyes, by displaying the most generous public spirit.” Such men are akin to the fuorusciti of Italian history or the Dutch Beggars of the Sea, the fortiets of party strife in the cities, who took to the sword because they had no other resource. Mutatis mutandis we may say as much for the intruders beyond the line, whom history calls the “Buccaneers” (q.v.). The “Vikings” (q.v.) were a portion of the Barbarian invasions. The “Barbary Pirates” (q.v.) stand apart. As for the piratical character of the commerce-destroyer, or privateer—why are we to brand Captain Fortunatus Wright, the Englishman who captures a French merchant ship, or Captain Robert Surcouf, the Frenchman who captures a British East Indiaman, as piratical, and not make the same reproach against Admiral Lord Howe, or Admiraal Don Luis de Córdoba, who with a fleet captures whole convoys? World, and who with a fleet captures whole convoys, or.

The pirate pure and simple is that member of an orderly community who elects to live on the sea, by violence and robbery, making no distinction between his own city or tribe and any other. The old adage, that “war makes thieves and peace hangs them” has ever been peculiarly true of the sea. War has always been conducted there by the capture of an enemy’s property, and by division of the spoil. A portion of the naval forces of all nations has been composed of privateers, letters of marque or corsairs, who plundered with a licence. They have ever found a difficulty in drawing the line between enemy and neutral; when peace returned some of them found it hard to be content with honest wages earned by dull industry. Nelson declared that all privateers were no better than pirates. He was borne out by the experience of Great Britain, which at the beginning of the Seven Years’ War had to take strong measures to repress the excesses of its privateers, and to hang a good few of them as mere pirates. The pirates suppressed by Pompey did not all submit to remain in the settlements he made. Some continued to rob at sea. If we can trust the Pastoral of Longus, and the other Greek romances, the pirate was a known type even under the Roman peace, but it is highly probable that he was more of a stock literary figure than a reality. Before the Roman peace, and during long centuries after it had been shattered, piracy was common. It grew out of a state of war. In modern times—even down to 1815—a recrudescence of piracy has followed regular hostilities. But there are other conditions which have a material influence, such as the need for a lucrative place and for a receiver of the plundered goods. An archipelago provides the best lurking-places, and next to it a coast of many inlets. Therefore the Greek Islands, the British Isles, the Antilles, the Indian Ocean, the coast of Cilicia in Asia Minor, of Dalmatia, of Malabar and of Norway, have all at one time or other, and some of them for centuries, been haunts of pirates. The convenience of the place had to be completely lost by the convenience of the harbours, the ancients had no means of attack. One city or tribe had little care for the sufferings of another. The men of the Cinque Ports who plundered the men of Yarmouth knew that their own townsmen would never call them to account, and therefore they had a safe refuge. Even when the medieval anarchy had come to an end on land, the sea was lawless. When peace was made with Spain after the death of Queen Elizabeth there were many who could not settle down to a life of industry. Some took the
plain course of betaking themselves to Algiers or Salec. But there were many who provoked nearer home. Sir William Monson, in his Naval Tracts, tells how he was sent in 1620 to hunt pirates out of the Channel. He sailed for Jamaica, and there a few persons, under his command, remained; and they were the forerunners of the Jamaica plantations. The English, who had a footing at sea near Scotland, but some employed, whom he shipped and used as guides and informers, on the coast of Ireland. At Broad Haven he discovered an Irish gentleman of the name of Cormat (presumably Cormac) living in some dignity. His house was the "well-head of all pirates," and their captains were the lovers of his daughters. Monson found agents of merchants of London and of Galway, who came to buy the goods which the pirates had to sell at a bargain. He put that interesting family under the gallows, and frightened them into turning king's evidence. It was his boast that he had cleared the Irish coast of pirates, but we know that they were common late in the reign of Charles I., and that under the name of "sea Tories" they abounded during the Civil War both in Ireland and in the Scilly Isles. Their existence was prolonged by the weakness of the government, which when piracy became very rampant took the disastrous course of offering pardon to all who would come in by a certain date. As a matter of course many did, and when their booty was spent returned to their piratical trade. Monson says that the pirates he caused to be executed had already tasted of the king's mercy. While there were friendly harbours to anchor in, purchasers to be met and a very fair prospect of a free pardon, piracy was not likely to cease.

As the 17th century drew on the law and the police became too strong for such persons as Mr Cormat at Broad Haven, and his pirate friends. But the pirate class did not cease. It was only driven to a wider field of operations—to a field which in fact stretched from the Red Sea to New England. On this wide portion of the earth's surface everything combined to favour the pirate. In the West Indies there was a "well-head" of immense capacity. Spain was forced late and reluctantly to recognize the legitimacy of any foreign settlement. She would rather put up with the lawless adventurers known as the "Brothers of the Coast" and the "Buccaneers" than co-operate with foreign governments to suppress them. Even when she renounced her full pretensions, several of the islands remained unoccupied except by the lingering remnants of the native races. Swine and cattle had been let loose on many of them, and had multiplied. The turtle was abundant and succulent. There was no want of food. A population with predatory instincts had been formed in the early days of hostile settlement and buccaneering. Jamaica was full of the so-called "private men-of-war" whose doings are prominent in the correspondence of the early governors, who were not uncommonly their associates. Add to this that the commercial policy of Spain denied to her colonists the right of trading with foreigners, and yet that she could not supply their needs herself. Hence arose a smuggling trade which had affinities with piracy. The lawless trader was not liable to be asked awkward questions, as to the origin of his cargo, by the Spanish American who purchased it on the sly for money or by barter. Nor were any questions asked him when he brought his cargo to Jamaica, San Domingo, the Carolinas, New England or even Europe. In the decay of Spain her navy was not to be feared. But it was not the commercial policy of Spain alone which helped the pirate. Great Britain, and France also, insisted that their colonists should trade exclusively with or through them. The colonists were always ready to buy "good cheap" from the smuggler, and never ask him whether the East Indian produce—tea, silk, spices and so forth—he offered for sale were purchased or plundered in the Red Sea or on the coast of Malabar or of Coromandel. Add to all this that the police and patrol work of regular navies was but superciliously done even in peace, and hardly at all in war, and that in the British colonies there was no judicial machinery for trying pirates till the 11th and 12th years of William III. (1700, 1701), and it will be seen that all the conditions favoured the pirate. In the East the decadence of the Mogul Empire was plunging India into anarchy, and it had no navy. Yet a large native trade existed, conducted by "Moores," as they were called, and Madagascar, a great "no-man's-land," afforded ample anchorage and food. To get passage on the coast, the Mats, and the East Indies to plunder the "Moores," to sell the booty in New England or the Carolinas to spend the produce in riotous living, and go to sea on the same errand again, was the round of life of the large class of known pirates, who formed a recognized element of the population of Massachusetts and New York at the end of the 17th century. These are the men we know best, for they were encouraged by the tolerance shown them to come into the light. Others are buried in, or only dimly visible in, obscurity. Some trace of these latter may be found in the Letter Books of the Old Providence Company, a puritan society formed in the reign of Charles I., of which Pym and the early Warwick, afterwards the Parliamentary admiral of the Civil War, were governors. It was founded to colonize Old Providence on the coast of Honduras, a place not to be confused with another pirate haunt, New Providence in the Bahamas. It took to plain piracy and was suppressed by the Spaniards in 1658. Warwick made a regular business and large profits byfitting out "privateers," which were in fact pirates on the "Spanish main," not the seas of America, as some have thought, but the coast of the mainland.

The lives of the later and better known pirates may be illustrated by the career of Captain Avery, or Every (alias Bridgeman), whose renown was great at the end of the 17th century, and who has left a lively inspired Delce's Life, Adventures and Piracies of Captain Singleton. Avery was a state of a Bristol ship hired by the Spaniards in 1694 to serve as a coastguard vessel in South America. She was called the "Charles II.," commanded by one Captain Gibson, and mounted 40 guns. While the "Charles II." was lying at Corunna, in company with another vessel also hired by the Spaniards, waiting for the payment of wages which was delayed, Avery persuaded part of the two crews to seize her and sail with her on a piratical voyage to the East. The enterprise was carried out without bloodshed or, apparently, coercion of those who were unwilling to go. Avery and his crew sailed to Madagascar, a regular haunt of the pirates. Many of them ended by remaining for life among the natives. The adventurers in the "Charles II.," who had already made some small prizes, English and Danish, were joined at the island by others of the same character who had come from the West Indies. From Madagascar they went to the Straits of Bab-el-Mandeb, to lie in wait for the trade from India. Several prizes were taken, and finally a large and valuable ship, belonging "to the Great Mogul and his subjects," was captured about ten miles from Surat. Avery and his crew now hastened to New England to sell their booty. The "Charles II." was disposed of as a privateer at Providence, and the pirates bought a sloop in which they sailed along the coast of the English colonies, selling their spoil, with the consent of the colonists and the connivance of the officials, who were bribed. In an evil hour for themselves they decided to come to England. The Indian governments, exasperated by the piracy practised at the expense of their subjects, were threatening reprisals on the East India Company. The Company made complaints to the government at home, and energetic measures of repression were taken. Avery himself escaped capture, but several of his men were brought to trial, condemned and executed. It is to be noted that when first tried, on the 19th of October 1696, they were acquitted. They were, however, re-tried on other counts, on the 31st of October. The charge of Lord Chief Justice Holt to the jury, and the address of Sir Charles Hedges, the recorder, to the jury, showed that both the importance and the uncertainty of securing a verdict.

The cruise of Avery is not only a typical example of a piratical venture, but it is an important date in the history of the policing of the sea. The English government was roused to a sense of the necessity for strong measures to repress piracy. All the steps taken were not according to knowledge. The extraordinary private venture of Lord Bellamont and his associates who sent out Captain Kidd (q.v.), a man of piratical antecedents,
to suppress pirates in the Eastern seas, brought deserved discredit upon them. The decision taken on the advice of Burchett, the secretary of the admiralty, to offer a pardon to all who would surrender by a given date—for all pirates committed before the 30th of April to the east of the Cape of Good Hope, and the 30th of June 1699 to the west—was an error. It induced many to come in, but it also gave all pirates the hope that they would in the future be provided with similar means of escape. The establishment of admiralty courts in the East Indies and America, and the despatch of warships were more effectual methods. Yet it was long before piracy was thoroughly checked; indeed the signing of the Peace of Utrecht was followed by a recrudescence of this form of crime. The privateers who swarmed in the West Indies, as well as the war lasted, used, in the phrase of the time, to join the squadrons of war-ships “on the plundering account,” could not settle down to dull industry. They leagued themselves to a species of pirate republic, with its capital at Providence in the Bahamas. In 1718 a special force had to be sent against them under Woodes Rogers, who is best remembered now for having taken Alexander Selkirk from the island of Juan Fernandez, in the course of a privateering voyage into the Pacific with the “dude” and “duchess” of Bristol. Rogers broke up the Providence settlement, and did a similar piece of service on the coast of Madagascar. Piracy did not, however, die. The Asiento (q.v.) Treaty having given Great Britain a monopoly of the slave trade with Spanish America, the monopolists, i.e., the South Sea Company and Royal African Company, were of course subject to the competition of interlopers. The interlopers were the natural friends of the pirates, who divided their activity between the Antilles and the west coast of Africa, plundering in the second, selling and re-fitting, not without further plunder, in the first. The most notorious of these free-booters was Bartholomew Roberts, who was introduced to piracy by Howell Davis. Roberts was the nearest known approach to the pirate of romance, ostentations, brave, not without touches of generosity. He was killed in action with Captain Chaloner Ogle, of H.M.S. “Swallow,” on the coast of Africa, in 1722.

As the American colonies grew more settled piracy became intolerable to them. Yet it lingered on the coast of North Carolina, where the pirates could either terrorize the scattered inhabitants, or were encouraged by dishonest officials. Here flourished the grotesque brute known as Blackbeard, Edward Teach, till his downfall on board his flagship in 1718. It was noted that several of those who helped to suppress him afterwards “went a-pirating” themselves. So strong was the piratical tradition of the New World that even men of some standing fell into it. “Major” or Captain Stede Bonnet, who was condemned and executed at Charleston, South Carolina, as a pirate, in 1718, was a gentleman of some property in Barbadoes, who first ventured to sea in a ship of his own. Stede Bonnet had taken advantage of an act of grace, had come in on a proclamation, and had returned to a pirate’s life. The last great explosion of piracy in the West Indies followed the peace of 1815. Here again we find the old conditions of operation, the safe lurking-place and the receiver. The refuge and market were supplied by the Spanish colonies, which were plunged into anarchy by their revolt against Spain. The pirates were able to masquerade as “patriot” navies. The sloth and corruption of Spanish captains-general of Cuba were no less favourable to the pirates. The south coast of the island became a haunt of these villains till the British and American governments were driven to combine for their suppression. When they had been followed into their hiding-places and their vessels sunk, they took to brigandage on land, and were harried by the Spanish authorities in self-defence. The pirates were able to rely on the support of some Spanish subjects, and the Malays were not named till nearly 1850. On the coast and the rivers of China piracy was and is endemic, but the sailing junk has no chance with the modern steamer. When cases of piracy have occurred in the Straits of Malacca or in the China seas, by which Europeans have been the sufferers, the crime has generally been perpetuated by men who shipped as passengers or as crew, and who surprised the vessel. The pirate has been as useful to the author of modern tales and poems as to the writers of the Greek romances. When he is seen in authentic evidence he is found to have been for the most part a pitiful rogue. His gains were but small. A share of £200 was wealth to a mere sailor, and one of £1000 wealth beyond the dreams of average privateers. If he could help it, and indeed nothing is more surprising than his readiness to surrender, when before the fate when he was the gallows.

Authorities.—The pirates of the ancient world are admirably dealt with in Mommsen’s History of Rome. For the modern pirate, see Monson’s “Naval Tracts” in Churchill’s Voyages, v. 5 (London, 1706), and the Newgate Calendar. For the earliest records of the Indian Wars; with an account of the Rise, Progress, Strength and Forces of Angria, the Pirate, &c., by Clement Downing (London, 1757) is useful. For PIRKE Aboth. The penultimate tract of the fourth part of the Mishnah is the booklet of proverbs in five chapters called Maasechet Aboth (tractatus patrum), better known with a sixth chapter as Pirke Aboth (capitula patrum). For Pirke Aboth in English see The Authorised Daily Prayer Book of the united Hebrew congregations of the British Empire, with a new translation by the Rev. S. Singer. The six chapters are there appointed to be read one on each Sabbath afternoon between Passover and New Year. Formerly they were read, in places at least, on the six Sabbaths between Passover and Pentecost only. The subsections of the chapters are hereinafter numbered as in the Authorized Prayer Book.

Chapters i., ii.—The Mosaic succession has first to be established. Moses (i. 1-3) having received the Torah from Sinai, it was handed down to Joshua, the Elders (Josh. xxiv. 31), the Prophets and the men of the Great Synagogue, from one of the last of whom, Simon Justus, it was received by Antigonus of Socho. Next are named (i. 4-15), without any title, as links in the chain of tradition, five pairs of teachers, the last Hillel and Shammai, elsewhere in the Mishnah called mundi pares (Surenh. iv. 324). Rabban Jochanan ben Zaccai (ii. g) “received from Hillel and Shammai.” Sayings begin with the words of their somewhat younger contemporary, Rabbi Tarphon (Tarahon), to the effect Aris longa vita brevis. These sections (i. 1-15, ii. 9-21) contain the Kern der Sammlungen (Strack). The words of the five pairs of teachers are sometimes interpolated (i. 6-ii. 8) of Rabban Gamaliel I., Rabban Simeon, “Rabbi,” i.e., R. Judah ha-Nasi (cent. a.d. 1-2), the traditional redactor of the Mishnah, Rabban Gamaliel II. and Hillel, which break the sequence.

Chapters iii., iv.—Maxims of numerous authorities, mostly Mishnah teachers and called Rabbis (Matt. xxi. 7 seq.; J. F. p. 27), not in exact chronological order.

Chapters v. vi.—Chap. v. which is sui generis, is presumably of later date than what precedes. Naming no teacher until the end, it combines historical, legendary and didactic elements. It touches upon the miraculous and its place in nature (v. 9). In form it is divided into sections, or paragraphe, from the ten creative Sayings to the trials of qualities which differentiate the disciples of Balaam and Abraham. R. Jacob ben Shimon’s commentary makes Aboth end with the saying of Judah ben Tuma (v. 23), “He bowl it as the hart, and he run it as the lion, and strong as a lion, to do the will of thy Father who is in heaven.” Chapter vi., on acquisitio legis, is thought to have been added for use on the last of the six sabbaths between Passover and Pentecost, J. F. Ap. p. 61). In some manuscripts there are seven chapters.

Pirke Aboth serves as a primer to the student of rabbinical Judaism. For the most part in simple Hebrew, it has a few sayings in Aramaic (i. 13-ii., 7 v. 25, 26) and some adopted Greek sayings from the Targum. There is an appendix (Chapters v. 27-31), which is also called Pirke Aboth and in which there is a discussion of the mode of death of gallery. He who would be pious should consult the dicta of Aboth (Baba Kam. 30a). It gives favourite aphorisms of leading Jewish teachers who flourished in or before the earliest Christian centuries, and supplies material for some interesting illustrations of the New Testament. Too heterogeneous to be represented by a few extracts, the collection
Pirmasens—Piroq, or Piergous (the French and Spanish forms respectively of a Caribbean word for this type of vessel; it has at various times been variously corruptly formed, e.g., petiçugaro, petty-pagar), originally the native name of a vessel made by hollowing out the trunk of a tree, a "dug-out"; hence applied to many different developments of this type of vessel used in the West Indies and along the American coast. An early improvement was to split the "dug-out" into two sections and insert a flat bottom of planking to widen it; another form had a leeboard, was decked in at either end, and had two masts.

Piron, ALEXIS (1680-1773), French epigrammatist and dramatist, was born at Dijon on the 9th of July 1680. His father, Aimé Piron, was an apothecary, who wrote verse in the Burgundian patois. Alexis began life as clerk and secretary to a banker, and then studied law. In 1719, when nearly thirty years old, he went to seek his fortune at Paris. An accident brought him money and notoriety. The jealousy of the regular actors produced an edict restricting the Théâtre de la Foire, or licensed booths at fair times, to a single character on the stage. None of the ordinary writers for this theatre would attempt a monologue-drama for the purpose, and Piron made a great success with a piece called Arlequin Deucalion, representing Deucalion immediately after the Deluge, amusing himself with recreating in succession the different types of man. In 1728 he produced Les Fils ingrats (known later as L'Écoute des pères) at the Comédie Française. He attempted tragedy in Callisthène (1750), Gustave Vasa (1753) and Fernando Cortes (1744), but none of these succeeded, and Piron returned to comedy with La Mère-manne (1758), in which the hero, Damis, suffers from the verse mania. His most intimate associates at this time were Mlle Quinault, the actress, and her friend Marie Thérèse Quendon, known as Mlle de Bar. This lady was slightly older than Piron and not beautiful, but after twenty years' acquaintance he married her in 1741. He died on the 21st of January 1773, in his eighty-fourth year. He was elected in 1753 to the Academy, but his enemies racket up a certain Ode à Triste, dating from his early days, and induced Louis XV. to interpose his veto. Piron however was dismissed, and during the last half-century of his life was never in any way. His best title to remembrance lies in his epigrams. The burlesque epistle on himself, in which he ridicules the Academy—

"Ci-gît Piron, qui ne fut rien,
Pas même académicien"—

is well-known, while many others are as brilliant. Grimm called him a "machine à sallisses."

Piron published his own theatrical works in 1758, and after his death his friend and literary executor, Rigole, de Juigny, published his Oeuvres complètes. M. Bonhomme produced a critical edition in 1859, completed by Polies choisies et pièces inédites in 1865.

Pirna, a town in the kingdom of Saxony, on the left bank of the Elbe, 11 m. above Dresden, and on the railway to Bodenbach and Prague. Pop. (1905), 19,226. The town is regularly built, with promenades covering the site of the old fortifications; the most notable edifices are the fine Gothic parish church, built in the 16th century and restored in 1806, and the old town-hall. Excellent sandstone is found on both banks of the Elbe. There are manufactures of glass, machinery, cigars, pottery and enamelled goods; and there is a trade in grain, fruit and timber, mainly carried on by river, and a little shipbuilding. Pirna, originally a Slavonic settlement, was for many years in the alternate possession of Bohemian and Meissen, but it became permanently united with the latter, and thus with Saxony, in 1405. The Sonnenstein, a fortress on a commanding eminence above the town, was erected in the 16th century on the site of an older castle by the elector of Saxony, Augustus I. It was once considered the most important fortress on the Elbe, and successfully withstood the Swedes in 1639, but it was captured and dismantled by the Prussians in 1758, and in 1813 was occupied by the French.

Pirmasens, a town of Germany, in the Bavarian Palatinate, 40 m. W. of Spire, on the railway from Biebermühle. Pop. (1905), 34,002. The only noteworthy buildings are the town-hall and the principal Evangelical church, which contains a fine monument to Louis IX. (d. 1278), landgrave of Hesse-Darmstadt, who made the town his residence. The staple industry is the production of boots and shoes; but musical instruments, leather and machines are also manufactured. Pirmasens owes its name to a St Firmin, who is said to have preached Christianity here in the 8th century. It originally belonged to the count of Hanau-Lichtenberg, but passed to Hesse-Darmstadt in 1736. In September 1793 the Prussians gained a victory here over a body of French troops.

See T. Weiss, Pirmasens in der Franzosenzeit (Pirmasens, 1895).

Pirméz, Octave (1834-1883), Belgian author, was born at Châtelineau in 1834. He belonged to a well-known Belgian family, and his cousin, Édouard Pirméz, was distinguished for his works on literature and political science. He lived an unhappy life at his château of Acoz, in Hainaut, where he died in May 1883. Pirméz was an ardent admirer of the French romanticists. His works include Les Feuillées: pensées et maximes (1862); Victor Hugo (1863); Jours de solitude (1860); Rémi: Souvenirs d'un frère (1880); Heures de philosophie (1881); and the posthumous Lettres à José (1884). These books form a history of his emotional life, and reveal an extreme melancholy.

See Vie et correspondance d'Octave Pirméz (1888), by Adolphe Siret and J. de Coppin.

PIROT (Turkish Shehr-Kec), a Servian town, 124 m. from the Bulgarian frontier at Tsaribrad, on the railway line between Nish and Sofia. Pop. (1900), 10,428. Pirat is the seat of the prefecture for the department of the same name, with a tribunal, several schools and a custom-house. It is the only proper industrial town in Servia, having numerous small factories for the manufacture of thin cloth (shayak), woolen braid (gaytan), and especially carpets. Its carpets have a great reputation in the Balkan Peninsula for their quaint designs, durability and freshness of colour. Pirat has a medieval fortress, believed to be the best in Bulgaria; the town has an important position on the military road leading from Old Naisus to Philippopolis. The town is of great strategical importance, for which reason the Russian plenipotentiaries at the Berlin congress (1878) stubbornly tried to include it within the Bulgarian frontier, while Austria and some other Powers insisted that it should be given to Servia. In the war between Servia and Bulgaria in 1885 the Bulgarians occupied and held it until the conclusion of peace.
PISA

PISA, a town, archiepiscopal see and capital of a province of the same name, Tuscany, Italy, on the Arno, 7 m. from the sea1 and 40 m. west of Florence by rail. Pop. (1881), 42,779; (1900), 61,279. It still retains its ancient walls, 61 m. in circuit, and is defended by a citadel on the south-west. The principal streets run alongside the river, and are lined with fine buildings. Besides the cathedral, the baptistery and the famous leaning tower, the city possesses several notable churches, as the Renaissance church of the Tuscan order of St Stephen, built in 1562 from plans by Vasari; San Niccolò, with a four-storied tower (1330), built by Niccola Pisano, and the tomb of Dante, pain, by Giovanni di ser Lippo, Spina; Santa Caterina (1626); Santa Maria della Spina, in the Italo-Gothic style, built in 1230 and restored in 1872; San Sepolcro, erected in 1150 by Diotisalvi; San Francesco, with frescoes by Taddeo Gaddi; and the basilica of San Michele (1018). Amongst the secular buildings may be mentioned the royal palace; the archiepiscopal palace; the palace of the order of St Stephen, built by Niccola Pisano and reconstructed by Vasari; the Upezzinghi (formerly Lanfreducci) palace, built of Carrara marble in 1500; the Lanfranchi, Agostini and other palaces; the university (1472); a large hospital (1528); and fine market hall. The Cathedral (1155-1278), Francavilla, Archduke Leopold, and Ferdinand I. The city possesses in an academy of the fine arts, with a gallery of paintings; and the university a library of 126,000 volumes, a national history museum, botanical garden and agricultural schools. The university, founded in 1338, has faculties of law, medicine, mathematics and philosophy and literature, and is to this day one of the most famous in Italy.

The architects of the cathedral were Boschetto and Rinaldo, both Italians, probably Pisans. It is in plan a Latin cross, with an internal length of 311 ft. and a breadth of 252 ft. The nave, 100 ft. thick, has eight sides, and the transepts single aisles; and at the intersection of nave and transepts there is a cupola. The basilica is still the predominant type, but the influence of the domed churches of Constantinople and the mosques of Palermo is also apparent. The pillars which support the nave are of marble from Elba and Giglio; those of the side aisles are the spoils of ancient Greek and Roman buildings brought by the Pisans galleys. Externally the finest part of the building is the west front, in which the note struck by the range of arches running round the base is repeated by four open arcades. Of the four doors there are three by John of Bologna, who was greatly helped by Francavilla, Tacco and others; the fourth, of the other side, of vaulted and this generally supposed to be the work of Bonanno. Of the interior decorations it is necessary to mention the altars of the nave, said to be after designs by Michelangelo, and the mosaics in the dome and the apse, which were among the best work of their age. The cathedral was built 1128, and marred in the 14th century by the introduction of Gothic details. The building is a circle 100 ft. in diameter, and is covered with a cone-surmounted dome 190 ft. high on which stands a spire, 200 ft. high. The range of second order of arches consists of twenty columns and the second of sixty; and above this is a row of eighteen windows in the same style separated by as many pilasters. In the interior, which is supported by four pillars and eight columns, the most striking features are the octagonal font and the hexagonal pulpit, erected in 1260 by Niccola Pisano. The campanile or ‘leaning tower of Pisa’ is a round tower, the noblest, according to Freeman, of the southern Romanesque. Though the walls at the base are 20 ft. thick and at the top about half as much, they are constructed throughout of mortar. The basement is surrounded by a range of semicircular arches supported on the columns and abutted against the octagonal columns. The eighth storey, which contains the bells, is of smaller diameter than the rest of the tower, and has only twelve columns. The height of the tower is 179 ft., but the ascent is extremely steep; and the visitor hardly needs the assistance of the inclinometer till he reaches the top and from the lower edge of the gallery looks ‘down’ along the shaft receding to its base. The tower leans or deviates from the perpendicular, to a striking extent, which has been measured of the perpendicular when measured in 1829, and 169 ft. in 1910. There is no reason to suppose that the architects, Bonanno and William of Innabrunck, intended that the campanile should be built in an oblique position; it is possible that they assumed the work would continue the progress. The foundations are not more than 10 ft. deep, and their circumference only that of the tower. The Campo Santo, lying to the north of the cathedral, owes its origin to Archbishop Ubaldo (1188-1200), who made the spot peculiarly sacred by bringing fifty-three shiploads of earth from Mount Calvary. The building, erected in the Italian Gothic style between 1278 and 1283, by Giovanni Pisano, is of special interest chiefly for its famous frescoes.

There are numerous industries, the most important being the manufacture of cottons. In the vicinity are the royal stud-farm (horses and dromedaries) of Cascine di San Rossore, and the mineral baths of San Giuliano, alkaline-ferruginous, with temperature 104° to 105° F.; and near nearby a steampower. At the mouth of the Arno, joined to the city by a steam tramway, is the seaside resort of Marina di Pisa, also known as Bocca d’Arno, a well-known centre for landscape painters.

The old town occupied the site of the ancient Pisaec on the right bank of the Arno. The foundation of Pisae is by tradition ascribed to a very remote period, and it was often (possibly only owing to the similarity of name) believed to have been founded from Pisae in Elis. It is first mentioned in history as the place at which a Roman army from Sardinia landed in 225 B.C., its harbour being at the mouth of the south branch of the Arno, north of Livorno. Being situated on the coast road (Via Amelia) it was important as a frontier fortress against Liguria, to which, and not to Etruria, it really belonged, perhaps, up to the time of Sulla, the actual boundary lying between it and Vada Volaterrana (mod. Vada). It became a colony in 180 B.C., and was important for the fertility of its territory, for its quarries, and for the timber it yielded for ship-building. Augustus gave it the name of Colonia Julia Pisana; his grandsons Gaius and Lucius were patrons of the colony, and after their death monuments were erected in their honour, as is recorded in two long inscriptions still extant. Greek vessels have been found within the city itself, seeming to point to the presence of Etruscan towns (C. Giraldini in Notizie degli Scavi, 1892, 147), but there remains now except of the Roman period—some scanty ruins of baths and of a temple, while the Piazza dei Cavalieri follows the outline of the ancient theatre.

See E. Bornmann, Corp. inscr. lat. xi. 272 (1888).

Little is known of the history of Pisa during the barbarian invasions, but it is an ascertained fact that it was one of the first towns to regain its independence. Under the Byzantine dominion Pisa, like many other of the maritime cities of Italy, profited by the weakness of the government at Constantinople to reassert its strength. And even during the first years of the harsh Lombard rule the need recognized by these oppressors of defending the Italian coast from the attacks of the Byzantines was favourable to the development of the Pisan navy. Few particulars are extant concerning the real condition of the town; but we occasionally hear of it as a republic, a new name by which it was known. It was an independent city, at moments when Italy was overwhelmed by the greatest calamities. According to Amari’s happy expression, “it was already independent by sea, while still enslaved on land.” Its prosperity notably declined after the establishment of the Lombard rule and under the Franks. It again began to flourish under the marquises of Tuscany, who governed it in the name of the emperor.

In 1003 we find records of a war between Pisa and Lucca, which, according to Muratori, was the first waged between Italian cities in the middle ages. But the military development and importance of Pisa in the 11th century, must be ascribed to the continuous and desperate struggle it maintained against the tide of Saracen invasion from Sicily. And, although the numerous legends and fables of the old chroniclers disguise the true history of this struggle, they serve to attest the importance of Pisa in those days. In 1004 the Saracens forced the gates and sacked a quarter of the town; and in 1011 they renewed the attack. But the Pisans repulsed them and assumed the offensive in Calabria, Sicily, and even in Africa. Still more memorable was the expedition afterwards undertaken by the united forces of Pisa and Genoa against Mogadish, better known in the Italian chronicles as Mugeto. This Moslem chief had made himself master of Sardinia, and was driven thence by the allied fleets in 1015. Again invading the island, he was again attacked and defeated by the same adversaries, leaving a
PISA

brother and son, or, as some authorities aver, a wife and son, prisoners in their hands. Sardinia continued to be governed by native "judges" who were like petty sovereigns, and were now subject to the sway of Pisa. This was the primary cause of the jealousy of the Genoese, and of the wars afterwards made by them upon Pisa and carried on until its power was crushed. Meanwhile the Pisans flourished more and more, and continued hostilities against the Saracens. In March, their ships returned from Palermo laden with spoil. Thus it is not surprising that Pisa should already have had its own code of laws (Consuetudini di mare), which in 1175 were approved by Gregory VII., and in 1261 confirmed by a patent from the emperor Henry IV., a document which mentions for the first time the existence of a magistrate analogous to the consuls of the republic, although the latter, according to some writers, already existed in Pisa as early as the year 1089; the point, however, is doubtful, and other writers place the first authentic mention of the consuls in the year 1094. The oldest of Pisan statutes still extant is the Breve dei consoli di mare of 1162.

In 1199 the Pisans joined in the second crusade, proved their valour at the capture of Jerusalem, and derived many commercial advantages from it; for within a short time they had banks, consuls, warehouses and privileges of all kinds in every Eastern port. Thus, while the commune of Pisa was still under the rule of the marqueses of Tuscany, all negotiations with it were carried on as with an independent state officially represented by the archbishop and consuls. The aristocrats were the dominant party, and filled the highest offices of the republic, which, in the 12th century, rose to great power, both on sea and land, by its wars with the Lucchese, Genoese and Moslems. In 1110 Pisa made peace with Lucca after six years of continuous hostilities. And in the years 1113 and 1115 it achieved a still greater enterprise. The Pisan fleet of three hundred sail, commanded by the archbishop Pietro Moriconi, attacked the Balearic Isles, where as many as 20,000 Christians were said to be held captive by the Moslems, and returned loaded with spoil and with a multitude of Christian and Moslem prisoners. The former were set at liberty or ransomed, and among the latter was the last descendant of the reigning dynasty. The chief enmity which had governed Majorca perished in the siege. Immediately afterwards the fourteen years' war with Genoa broke out. The two republics contested the dominion of the sea, and both claimed supreme power over the islands of Corsica and Sardinia. The naval edict granting the supremacy of Corsica to the Pisan church proved sufficiently forcible for the war, which went on from 1118 to 1131. Then Innocent II. transferred the supremacy over part of Corsica to the Genoese church, and compensated Pisa by grants in Sardinia and elsewhere. Accordingly, to gratify the pope and the emperor Lothair II., the Pisans entered the Neapolitan territory to combat the Normans. They aided in the vigorous defence of the city of Naples, and twice attacked and pillaged Amalfi, in 1135 and 1137, with such effect that the town never regained its prosperity. It has been said that the copy of the Pandects then taken by the Pisans from Amalfi was the first known to them, but in fact they were already acquainted with the Moslem laws. This, together with Genoa never came to a real end. Even after the retaking of Jerusalem by the Moslems (1187) the Pisans and Genoese again met in conflict in the East, and performed many deeds of valour. They were always ready to come to blows, and gave still more signal proofs of their enmity during the Sicilian War in behalf of the emperor Henry VI. From that moment it was plain that there could be no lasting peace between these rival powers until the one or the other should be crushed. The greatness and wealth of the Pisans at this period of their history is proved by the erection of the noble buildings by which their city is adorned. The foundations must be remembered that the Pisans and Florentines dated the beginning of the year 27th of March, instead of the 25th of March from which the Genoese had always dated. But the Florentines dated it from the 25th following and the Pisans from the 25th of March preceding the commencement of the common year. The new or common style was adopted throughout Tuscany in the year 1790.
Elba, thereupon Genoa. In 1276 the Pisans were compelled to agree to very grievous terms—to exempt Florentine merchants from all harbour dues, to yield certain strongholds to Lucca, and to permit the return of Count Ugolino, whose houses they had burnt, and whose lands they had confiscated. Thus the count again became a powerful leader in Pisa. Visconti, however, was dead.

This was the moment chosen by Genoa for a desperate and decisive struggle with her perpetual rival. For some years the hostile fleets continued to harass each other and engage in petty skirmishes, as if to measure their strength and prepare for a final effort. On the 6th of August 1284 the great battle of Meloria took place. Here seventy-two Pisan galleys engaged eighty-eight Genoese, and half the Pisan fleet was destroyed. The chroniclers speak of 5000 killed and 17,000 prisoners; and, although these figures must be exaggerated, so great was the number of captives taken by the Genoese as to give rise to the saying—"To see Pisa, you must now go to Genoa." This defeat crushed the power of Pisa. She had lost her dominion over the sea, and the Tuscan Guelphs again joined in attacking her by land. Count Ugolino had taken part in the battle of Meloria and was accused of treachery. At the height of his country's disasters he sought to confirm his own power by making terms with the Florentines, by yielding certain castles to Lucca, and by neglecting to conclude negotiations with the Genoese for the release of the prisoners, lest these should all prove more or less hostile to himself. This excited a storm of opposition against him. The archbishop Ruggieri, having put himself at the head of the nobles, was elected podesta by the Lanfranchi, Sismondi and Guanandi, and a section of the popular party. The city was plunged into civil war. The great bell of the commune called together the adherents of the archbishop; the bell of the people summoned the partisans of the count. After a day's fighting (July 1, 1288) the count, his two sons and his two grandsons were captured in the palazzo del popolo (or town hall), and cast into a tower belonging to the Guanandi and known as the "Tower of the Seven Streets." Here they were all left to die of hunger. Their tragic end was afterwards immortalized in the Divina commedia. The sympathies of Dante Alighieri, the Florentine patriot and foe of Rome, were naturally in favour of the victims of an aristocratic prelate, opposed to all reconciliation with Florence.

The Florentines were now allied with Lucca and Genoa, and a few of their vessels succeeded in forcing an entry into the Pisan port, blocked it with sunken boats, and seized its towers. Their own internal dissensions of 1293 put a stop to the campaign, but not before they had concluded an advantageous peace. They and all the members of the Guelph league were freed from all imposts in Pisa and its port. In addition to these privileges the Genoese also held Corsica and part of Sardinia; and throughout the island of Elba they were exempted from every tax. They likewise received a ransom of 160,000 lire for their Pisan prisoners. These were no longer numerous, many having succumbed to the hardships and sufferings of all kinds to which they had been exposed.

In 1312 the arrival of the emperor Henry VII, gladdened the hearts of the Pisans, but his sudden death in 1313 again overthrew the whole government. Ugolino della Faggionella remained as imperial lieutenant, was elected podesta, and captain of the people, and thus became virtual lord of the city. As a Ghibelline chief of valour and renown he was able to restore the military prestige of the Pisans, who under his command captured Lucca and defeated the Florentines at Montecatini on the 29th of August 1315. So tyrannical, however, was his rule that in 1316 he was expelled by the popular fury. But Pisa's freedom was for ever lost. He was succeeded by other lords or tyrants, of whom the most renowned was Castruccio Castracane, a political and military adventurer of much the same stamp as Ugolino himself. With the help of Louis the Bavarian, Castruccio became lord of Lucca and Pisa, and was victorious over the Florentines; but his premature death in 1328 again left the city a prey to the conflicts of opposing factions. New lords, or petty tyrants, rose to power in turn during this period of civil discord, but the military valour of the Pisans was not yet extinguished. By sea they were almost impotent—Corsica and Sardinia were lost to them for ever; but they were still formidable by land. In 1341 they besieged Lucca in order to prevent the entry of the Florentines, to whom the city had been sold for 250,000 florins by the powerful Mastino della Scala. Aided by their Milanese, Mantuan and Paduan allies, they gave battle to their rivals, put them to rout at Altopascio (Oct. 2), and then again excluded them from their port. Thereupon the Florentines obtained Porto Talamone from Siena and established a navy of their own. By this means they were enabled to capture the island of Giglio, and, attacking the Pisan harbour, carried off its chains, bore them in triumph to Florence, and suspended them in front of the baptismery, where they remained until 1848.

Then, in pledge of the brotherhood of all Italian cities, they were given back to Pisa, and placed in the Campo Santo.

The war was now carried on by the free companies with varying fortune, but always more or less to the hurt of the Pisans. In 1356 Lucca was taken from them by the emperor Charles IV; and afterwards Giovani Galeazzo Visconti, known as the count of Virtù, determined to forward his ambitious designs upon the whole of Italy by wresting Pisa from the Gambacorti. For at this time the conflicts of the Rasaptani faction, headed by the Gherardesca, with the Bergolfini led by the Gambacorti, had left the latter family masters of the city. At Visconti's instigation Piero Gambacorti, the ruler of the moment, was treacherously assassinated by Jacopo d'Appiano, who succeeded him as tyrant of Pisa, and bequeathed the state to his son Gherardo. The latter, a man of inferior ability and daring, sold Pisa to the count of Virtù, receiving in exchange 200,000 florins, Fiombino, and the islands of Elba, Pianosa and Monte Cristo. Thus in 1399 Visconti took possession of Pisa, and left it to his natural son Gabriele Maria Visconti, who was afterwards expelled from its gates. But even during this century of disaster the Pisans continued to cherish not only commerce, but also the fine arts. In the year 1327 they had entrusted the erection of their fine Campo Santo to Niccola and Giovanni Pisano, by whom the architectural part of it was completed towards the end of the century. In the following year the first artists of Italy were engaged in its decoration, and the celebrated frescoes attributed to Orcagna (q.v.) were painted on its walls. Others were afterwards supplied by Benozzo Gozzoli and men of lesser note, and the labour of ornamentation was only discontinued in 1464.

Meanwhile, in 1496, the Florentines made another attack upon Pisa, besieging it simultaneously by sea and land. Owing to the starving condition of its defenders, and aided by the treachery of Giovanni Gambacorti, they entered the city in triumph on the 9th of October, and sought to "crush every germ of rebellion and drive out its citizens by measures of the utmost harshness and cruelty." Such were the orders sent by the Ten of War to the representatives of the Florentine government in Pisa, and such was then the established policy of every Italian state. Consequently for a long time there was a continual stream of emigration from Pisa. The Medici pursued a humane course. In 1472 Lorenzo the Magnificent tried to restore the ancient renown of the Pisan university. To this end he provided with scholars who had only a few chairs of letters and philosophy in Florence, compelled theFlorentines to resort to Pisa for the prosecution of their studies. But nothing could now allay the inextinguishable hatred of the conquered people. When Charles VIII. made his descent into Italy in 1494, and came to Sarzana on his way to Tuscany, he was welcomed by the Pisans with the greatest demonstrations of joy. And, although that monarch was ostensibly the friend of Florence, they did not
PISA, COUNCIL OF—PIŠAČA LANGUAGES

hesitate, even in his presence, to assert their own independence, and, casting the Florentine ensign, the Marzocco, into the Arno, made instant preparations for war. Between 1499 and 1500, they heroically withstood three sieges and repulsed three attacking armies. But their adversaries always returned to the assault, and, what was worse, yearly laid waste their territories and destroyed all their crops. Soderini, who was perpetual gonfalonier of Florence, and Machiavelli, the secretary of the Ten, urged on the war. In 1500 Florence encamped her forces on three sides of the distrest city, which at last, reduced to extremity by famine, was compelled to surrender on the 8th of June 1500. Thenceforth the Florentines remained lords of Pisa. But now, mainly owing to the efforts of Soderini and Machiavelli, the conquerors showed great humanity. They brought within the town the stores of provisions, which were freely distributed to all; they tried to succour the suffering populace in every way, and gave other assistance to the wealthier classes. Nevertheless, emigration continued even on a larger scale than in 1466, and the real history of Pisa may be said to have ended.

In Naples, in Palermo, in all parts of Italy, Switzerland and the south of France, we still find the names of Pisan families who quitted their beloved home at that time. The Florentines immediately built a new citadel, and this was a great bitterness to the Pisans. The Medici, however, remained well disposed towards the city. Leo X. was an active patron of the university, but it again declined after his idea of the grand duke of a genuine statesman, not only restored the university, but instituted the "uffizio dei fassi," or drainage office for the reclamation of marsh lands, and founded the knighthood of St Stephen. This order played a noble part in the protection of Tuscan commerce, by fighting the Barbary pirates and establishing the prestige of the grand-ducal navy (see Medici). Under the succeeding Medici, Pisa's fortunes steadily declined. Ferdinand I. initiated a few public works there, and above all restored the cathedral, which had been partly destroyed by fire in 1593. These dreary times, however, are brightened by one glorious name—that of Galileo Galilei.

The population of Pisa within the walls had been reduced in 1551 to 8574 souls, and by 1745 it had only risen to the number of 12,406. Under the house of Lorraine, or more correctly during the reign of that enlightened reformer the grand duke Peter Leopold (1765-1790), Pisa shared in the general prosperity of Tuscany, and its population constantly increased. By 1849 it contained 21,670 souls, exclusive of the suburbs and outlying districts.

AUTHORITIES.—Paolo Tronci, Annali di Pisa, edited by E. V. Montauro (2 vols., Lucca, 1842-1843), which comes down to 1840, Ramberti Grosset., Pisa e le sue abitanti (Pisa, 1844), a useful historical guide; Ronconi, "Istorie Pisane," in the Archivio storico italiano, vol. vi., pt. 1; " Cronache Pisane," in the same Archivio, vol. vi., pt. 2; for the early constitution of the city, see G. Volpe's Storia delle istituzioni, comunali di Pisa (Florence, 1902), and for the laws, F. Bonaiuti's Statuti inediti della città di Pisa (3 vols., Florence, 1851, &c.). The maritime and commercial history of the republic is dealt with in A. Schaufuß's Das Konulat des Meeres in Pisa (Leipzig, 1888), and in Pawinski's Zur Entstehungsgeschichte des Konsulats in den Communken Nord- und Mittel-Italiens (Berlin, 1867); for the monuments and inscriptions see A. Da Montelone's Studi di epigrafia (Leghorn, 1868), and E. de Flotte, Les Monuments de Pise au moyen âge (Paris, 1866); also Repetti's Dizionario geografico della Toscana, s. v. "Pisa." For Dante's connexion with Pisa, see Dante e i Pisani, by Giovanni Sforza (Pisa, 1851), Among the more recent historical guides to Pisa of a popular character is The Story of Pisa and Lucca, by Janet Ross and Nellie Erichsen, in Dent's "Medieval Towns." (London, 1907), and T. B. Supino's Pisa, in the "Italia artistica Series." (P. V.)

PISA, COUNCIL OF (1409). The great schism of the west had already lasted thirty years, and the efforts which had been made to restore unity within the Church by the simultaneous resignation of the two rival pontiffs had been in vain, when in the spring of 1408, the state of affairs being desperate, the idea arose of assembling a council to effect a union without the co-operation of the popes. The initiative came from those cardinals who had one after the other secured either from Gregory XII. or Benedict XIII. They were forestalled by the popes, who each summoned a council, the former to Cividale (in Friuli), the latter to Perpignan, so the dissident cardinals sent out anantedated letter inviting all their colleagues to meet at the three cities of March 1409. Their appeal met with a response in a great part of Italy, France, Navarre, Portugal and England, and in Germany in the states subject to Wenceslas king of the Romans, the electors of Cologne and Mainz, the margrave of Brandenburg, &c. For a time the number of the fathers exceeded five hundred.

The day after the opening of the council, proceedings were started against the two popes, who, it was agreed, were to be eliminated. An act of accusation, containing in 37 articles the chief complaints against them, was read out to the people; not only the cardinals but the populace was addressed, and there was even an insinuation of sorcery. The purpose was in order to depose them with some show of legality, it was necessary, as a preliminary, to convict them of heresy, and it began to be seen that their tenacity of power, and the ruses by which they evaded the necessity of abdicating, however harmful might be their consequences, did not in themselves constitute a clearly-defined heresy. On the 5th of June 1409 was read the definitive sentence: that as heretics, and therefore separated from the Church, Pedro de Luna (Benedict XIII.) and Angelo Corrario (Gregory XII.) were ipso facto deposed from any office; they must not be obeyed, nor assisted, nor harboured. In the course of the rejoicings which followed this sentence among the populace of Pisa, occurred the somewhat scandalous event of the burning of two images crowned with parchement mitres, representing Gregory XII. and Benedict XIII. It was in vain that the ambassadors of Benedict XIII. presented themselves at Pisa. The crowd greeted their arrival with mockery and derision, and being treated as the envos of heretics they escaped without having obtained a hearing.

In order to complete their task the cardinals present at Pisa, authorized by delegation of the council, shut themselves up in conclave, and elected one of their number, Peter Philargus, cardinal of Milan, as the new pope, who assumed the name of Alexander V. They had hoped to save the Church, but unfortunately the result of their efforts, generous as they were, was that the schism increased in bitterness, and that instead of the unity for which the Church craved, three popes continued to flourish. Both the deposed pontiffs protested against the legality of the council of Pisa; each had numerous partisans, and the thesis, constructed rather to meet the exigencies of the case, which attributed to a synod assembled by the cardinals the right of constituting itself judge of a sovereign pontiff, was far from being established.

Originally the council of Pisa was to have occupied itself not only with effecting the union, but also with the reform of the Church. As a matter of fact, it confined itself to expressing certain desiderata in a "libellus supplicatorius" which it submitted to the new pope. Alexander V. only partially acceded to these demands, many of which constituted serious encroachments on the prerogative of the Holy See; he then declared the work of reform suspended, and dissolved the council (August 7, 1409).

Valois, La France et le grand schisme d'occident, iv. 3-107, 175 seq. (Paris, 1902).

PIŠAČA LANGUAGES, the name which has been given to a family of languages spoken immediately to the south of the Hindu Kush, and north of the frontier of British India. The family included the group of Kâfir languages spoken in Kafiristan, Khowar, spoken in the Chitral country, and the group of Shina languages, which includes the Shina of Gilgit, Khostâstan, spoken in the Kohistan of the Indus and Swat rivers, and Kashmiri. All of these Kashmiri is the only one which has received any literary cultivation, and of which the number of speakers is known. The Pišāca languages are Aryan by origin, but are neither Iranian nor Indo-Aryan. (See Indo-Aryan LANGUAGES and Kashmire.)

(G. A. Gr.)
PISACANE, CARLO, duke of San Giovanni (1818-1857), Italian revolutionary, was born at Naples, and entered the Neapolitan army in 1830; but having become imbued with Mazzinian ideas he emigrated in 1847, and after a short stay in England and France served in the French army in Algeria. The revolution of 1848 recalled him to Italy; he played a part in the brief but glorious history of the Roman Republic, and was the life and soul of the war commission in the defence of the city. After its capture by the French he again went into exile, first to London and then to Genoa, maintaining himself by teaching. He regarded the rule of the house of Savoy as no better than that of Austria. When Mazzini, underrated by the failure of the abortive Milan rising on the 6th of February 1853, determined to organize an expedition to provoke a rising in the Neapolitan kingdom, Pisacane offered himself for the task, and sailed from Genoa with a few followers (including Giovanni Nicotera) on board the "Cagliari" on the 25th of June 1857. They landed on the island of Ponza, where the guards were overpowered and some hundreds of prisoners liberated, and on the 28th arrived at Sapri in Calabria and attempted to reach the Citlento. But hardly any assistance from the habitants was forthcoming, and the invaders were quickly overpowered, Pisacane himself being killed.

See P. M. Bilotti, La Spedizione di Sapri (Salerno, 1907).

PISANO, CHRISTINE DE (1364-1413), French poet, of Italian birth, was born at Venice in 1364. When she was four years old she was brought to her father, a councillor of the Venetian Republic, in Paris, where he held office as ambassador to Charles V. At fifteen Christine married Étienne du Castel, who became Charles's notary and secretary. After the king's death in 1380 her father lost his appointment, and died soon after; and when Christine's husband died in 1389 she found herself without a protector, and with three children depending on her. This determined her to have recourse to letters as a means of livelihood. Her first ballads were written to the memory of her husband, and as love poems were the fashion she continued to write others—lais, virelais, rondeaux and jeux à vendre—but she took the precaution to assure her readers (Cend balades, No. 50) that they were merely exercises. In 1399 she began to study the Latin poets, and between that time and 1405, as she herself declares, she composed some fifteen important works, chiefly in prose, besides minor pieces. The earl of Salisbury, who was in Paris on the occasion of the marriage of Richard II. with Isabella of France (1396), took her elder son, Jean du Castel (b. 1384), and reared him as his own; the boy, after Salisbury's death (1400), being received by Philip of Burgundy, at whose desire Christine wrote Le Livre des faits et bonnes mœurs du sygley roy Charles 1 (1405), valuable as a first-hand picture of Charles V. and his court. Her Mutation de fortune, in which she finds room for a great deal of history and philosophy, was presented to the same patron on New Year's Day, 1424. It possesses an introduction of great autobiographical interest. In La Viron (1405) she tells her own history, by way of defence against those who objected to her pretensions as a moralist. Henry IV. of England desired her to make his court her home, and she received a like invitation from Galeazzo Visconti, tyrant of Milan. She preferred, however, to remain in France, where she enjoyed the favour of Charles VI., the dukes of Berry and Burgundy, the duchess of Bourbon and others.

Christine was a champion of her own sex. In her Dit de la rose (1402) she describes an order of the rose, the members of which bind themselves by vow to defend the honour of women. Her Épitre au dieu d'amour (1390) is a defence of women against the taunts of Jean de Meun, and initiated a prolonged dispute with two great scholars of her time, Jean de Monstreuil (d. 1415) and Gonthier Col, who undertook the defence of the Roman de la rose. Christine wrote about 1407 two books for women, La Cité des dames and Le Livre des trois versus, or Le Trésor de la cité des dames. She was devoted to her adopted country. During the civil wars she wrote a Lamentation (1410) and a Livre de la paix (1412-1413), but after the disasters of the campaign of Agincourt she retired to a convent. We have no more of her work until 1429, when she broke her silence to write a song in honour of Joan of Arc. Of the circumstances of her death nothing is known but it probably took place about this time. Her Cité des dames contains many interesting contemporary portraits, and her Livre des trois versus contains details of domestic life in the France of the early 15th century not supplied by more formal historians.

Her poems were edited by Maurice Roy for the Société des anciens Textes français (1886, etc.), and her Livre du chemin du long estâde, by Puschel (Berlin, 1887). There are monographs by Raimond Thomassy (Paris, 1838); E. M. D. Robinéau (Saint-Omer, 1882); and Friedrich Koch (Goslar, 1888). It is possible that Jean Castel, who was chancellor of France under Louis XI., was Christine's grandson. Hoccleve imitated her Épitre au dieu d'amour, in his "Letter of Cupid" (Chaucerian and other Pieces, ed. W. D. Skert, 1897). A translation of her Épitre d'Othea was made (c. 1440) by Stephen Scrope for his stepfather, Sir John Fastolf, and is preserved in a MS. at Longleat. This was edited (1904) for the Roxburghe Club by W. G. F. Warner as The Epistle of Othea to Hector, or the Boke of Kyngyhode. The Moral Proverbs of Christyne de Pise, translated by Earl Rivers, was printed in 1478 by Caxton, who himself translated, by order of Henry VII., her Livre des faicts d'armes, et des chevalerie, a treatise on the art of war, based chiefly on Vegetius. Her Cité des dames was translated by Brian Anslay (London, 1521).

PISANI, VETTOR (d. 1380), Venetian admiral, was in command of the Venetian fleet in 1378 during the war against the Genoese, whom he defeated off Capo d'Anzio; subsequently he recaptured Cattaro, Sebenico and Arbe, which had been seized by the Hungarians, the allies of the Genoese. But the Genoese fleet completely defeated Pisani at Pola in May 1379, and on his return to Venice he was thrown into prison. The enemy now pressed home their victory, and besieged and captured Chioggia, whereby Venice itself was in danger. The people thereupon demanded the liberation of Pisani, in whose skill they had the fullest confidence. The government gave way and appointed the aged commander admiral of the fleet once more. Through his able strategy and daring he recaptured Chioggia, defeated the Genoese and threatened Genoa itself until that republic agreed to peace terms. Pisani died in 1380 while on his way to Mannfredonia with a squadron to ship provisions.

PISANO, ANDREA, also known as ANDREA DA PONTADERA (c. 1270-1348), Italian sculptor, was born about 1270, and first learned the trade of a goldsmith. He became a pupil of Giovanni
that his chief works were executed, and the formation of his mature style was due rather to Giotto than to his earlier master. Of the three world-famed bronze doors of the Florentine baptistery, the earliest one—that on the south side—was the work of Andrea; he spent many years on it; and it was finally set up in 1336.1 It consists of a number of small quatrefoil panels—the lower eight containing single figures of the Virtues, and the rest scenes from the life of the Baptist. Andrea Pisano, while living in Florence, also produced many important works of marble sculpture, all of which show strongly Giotto's influence. In some cases probably they were actually designed by that artist, as, for instance, the double band of beautiful panel-reliefs which Andrea executed for the great campanile. The subjects of these are the Four Great Prophets, the Seven Virtues, the Seven Sacraments, the Seven Works of Mercy and the Seven Planets. The duomo contains the chief of Andrea's other Florentine works in marble. In 1347 he was appointed architect to the duomo of Orvieto, which had already been designed and begun by Lorenzo Maitani. The exact date of his death is not known, but it must have been shortly before the year 1349.

Andrea Pisano had two sons, Nino and Tommaso—both, essentially the former, sculptors of considerable ability. Nino was very successful in his statues of the Madonna and Child, which are full of human feeling and soft loveliness—a perfect embodiment of the Catholic ideal of the Divine Mother. Andrea's chief pupil was Andrea di Cione, better known as Orcagna (q.v.). Balduccio di Pisano, another, and in one branch (that of sculpture) equally gifted pupil, executed the wonderful shrine of St. Eustorgio at Milan—a most magnificent mass of sculptured figures and reliefs.

PISANO, GIOVANNI (c. 1250-1330), Italian architect and sculptor, was the son of Niccola Pisano. Together with Arnolfo del Cambio and other pupils, he developed and extended into other parts of Italy the renaissance of sculpture which in the main was due to his father's talent. After he had spent the first part of his life at home as a pupil and fellow worker of church of S. Domenico in 1324, but little of the original structure remains. The north transept, however, still contains his beautiful tomb of Benedict XI., with a sleeping figure of the pope, guarded by angels who draw aside the curtain. One of his most beautiful architectural works was the little chapel of S. Maria della Spina (now rebuilt, "restored"), on the banks of the Arno in Pisa; the actual execution of this chapel, and the sculpture with which it is adorned, was mostly the work of his pupils. The influence of his father Niccola is seen strongly in all Giovanni's works, but especially in the pulpit of S. Andrea at Pistoia, executed about 1300. Another pulpit, designed on the same lines, was made by him for the nave of Pisa Cathedral between 1310 and 1311. The last part of Giovanni's life was spent at Prato, near Florence, where with many pupils he worked on the northern tier of the Baptistery.
and kneeling figures of the Magi. Certain figures in others of the panels are less deeply imbued with classical feeling.

The next important work of Niccola in date is the Areca di San Domenico, in the church at Bologna consecrated to that saint, who died in 1221. Only the main part, the actual sarcophagus covered with sculptured reliefs of St Domenic's life, is the work of Niccola and his pupils. The sculptured base and carved roof, with its fanciful ornaments are later additions. This "Areca"

The Adoration of the Magi, one of the panels in the pulpit of the Pisan Baptistery, by Nicola Pisan. was made when St Domenic was canonized, and his bones translated; it was finished in 1267, not by Niccola himself, but by his pupils. The most magnificent, though not the most beautiful, of Niccola's works is the great pulpit in Siena cathedral (1268). It is much larger than that at Pisa, though somewhat similar in general design, being an octagon on cusped arches and columns. Its stairs, and a large landing at the top, with carved balusters and panels, rich with semi-classical foliage, are an addition of about 1500. The pulpit itself is much overloaded with sculpture, and each relief is far too crowded with figures. An attempt to gain magnificence of effect has destroyed the dignified simplicity for which the earlier pulpit is so remarkable.

Niccola's last great work of sculpture was the fountain in the piazza opposite the west end of the cathedral at Perugia. This is a series of basins rising one above another, each with sculptured bas-reliefs; it was begun in 1274, and completed, except the topmost basin, which is of bronze, by Niccola's son and pupil Giovanni.

Niccola Pisan was not only pre-eminent as a sculptor, but was also the greatest Italian architect of his century; he designed a number of very important buildings, though not all which are attributed to him by Vasari. Among those now existing the chief are the main part of the cathedral at Pistoia, the church and convent of Sta Margherita at Cortona, and Sta Trinità at Florence. The church of Sant' Antonio at Padua has also been attributed to him, but without reason. Unfortunately his architectural works have in most cases been much altered and modernized. Niccola was also a skilled engineer, and was compelled by the Florentines to destroy the great tower, called the Guardamorte, which overshadowed the baptistery at Florence, and had for long been the scene of violent conflicts between the Guelphs and Ghibellines. He managed skilfully so that it should fall without injuring the baptistery. Nicola Pisan died at Pisa in the year 1278, leaving his son Giovanni a worthy successor to his great talents both as an architect and sculptor.

Though his importance as areviver of the old traditions of beauty in art has been to some extent exaggerated by Vasari, yet it is probable that Niccola, more than any other one man, was the means of starting that "new birth" of the plastic arts which, in the years following his death, was so fertile in countless works of the most unrivalled beauty. Both Niccola and his son had many pupils of great artistic power, and these carried the influence of the Pisani throughout Tuscany and northern Italy, so that the whole art of the succeeding generations may be said to have owed the greater part of its rapid development to this one family.

See SCULPTURE, and general histories of Italian art; Symonds, Renaissance in Italy; A. Brach, Nicola und Giovanni Pisano und die Plastik des XIV. Jahrhunderts in Siena (Strassburg, 1904).

PISANO, VITTORE (c. 1380-1450), commonly called PISANELLO, Italian medalist, was a native of San Vigilio sul Lago in the territory of Verona. Specimens of his work as a painter are still extant in Rome, Venice, Verona and Pistoia, and entitle him to a place of some distinction in the history of that art. The National Gallery in London possesses a very fine specimen of Pisanello's work—a panel painted with miniature-like delicacy. During the latter portion of his life he lived in Rome, where he enjoyed great repute.

PISARUM (mod. Pesaro, q.v.), an ancient town of Umbria on the Via Flaminia, 26 m. from Ariminum and 8 from Fanum Fortunae. A Roman colony was founded here in the territory of the Galii Senones in 154 B.C., at the mouth of the river Pisarum (mod. Foglia); the sea has since then receded about half a mile. Whether it took the place of an earlier town or not, is not known: an important Gaulish cemetery has been discovered near the village of Novilara between Pisauro and Fanum, but to which of these centres (if either) it belonged is uncertain (E. Brizio in Monumenti dei Linei [1855], v. 85 sqq.). In 1744 B.C. we hear that the census built a temple of Jupiter here and paved a road. T. Accius, the counsel who opposed Cicero in the case when he defended Cluentius in a still extant speech, was a native of Pisauro. Catullus refers to the town as decadent or unhealthy, but this may be merely malicious, and does not seem to be born out by facts: for it is not infrequently mentioned by classical authors. It was occupied by Caesar in 49 B.C., and was made a colony under the second triumvirate. Hence it bears the name Colonia Julia Felix. We hear little of it under the empire. It was destroyed by the Goths in 539, and restored by Belisarius in 545. From the inscriptions, nearly 260 in number, an idea of the importance of the town may be gained. Among them are a group of tappi found on the site of a sacred grove of the matrons of Pisauro, bearing dedications to various deities, and belonging probably to the date of the foundation of the colony. There are some remains of the town walls, and an ancient bridge over the Foglia. It was, like Ariminum, a considerable place for the manufacture of bricks and pottery, though the factories cannot always be precisely localized.

PISCES (the fishes), in astronomy, the twelfth sign of the zodiac (q.v.), represented by two fishes tied together by their tails, and protected by the symbol ♓. It is also a constellation, mentioned by Eudoxus (4th century B.C.) and Aratus (3rd century B.C.); and catalogued by Ptolemy (38 stars), Tycho Brahe (36) and Hevelius (39). In Greek legend Aphrodite and Eros, while on the banks of the Euphrates, were surprised by Typhon, and sought safety by jumping into the water, where they were changed into two fishes. This fable, however, as in many other similar cases, is probably nothing more than an adaptation of an older Egyptian tale. a Piscium, is a fine double star of magnitude 3 and 4; 35 Piscium, is another double star, the components being a white star of the 6th magnitude and a purplish star of the 8th magnitude.

Piscis australis, the southern fish, is a constellation of the southern hemisphere, mentioned by Eudoxus and Arabus, and catalogued by Ptolemy, who described 18 stars. The most important star is a Piscis australis or Fomalhaut, a star of the first magnitude.

Piscis volans, the flying fish, is a new constellation introduced by John Bayer in 1603.

PISCICULTURE (from Lat. piscis, fish). The species of fish which can be kept successfully in captivity throughout their lives from egg to adult is exceedingly limited in number. The various breeds of goldfish are familiar examples, but the carp is almost the only food-fish capable of similar domestication. Various other food-fishes in both marine and fresh-water, can be kept in ponds for longer or shorter periods, but refuse to breed, while in other cases the fry obtained from captive breeders will not develop. Consequently there are two main types of pisciculture to be distinguished: (1) the rearing in confinement of young fishes to an edible stage, and (2) the stocking of natural waters with eggs or fry from captured breeders.
Fish-rearing.—Of the first type of pisciculture there are few examples of commercial importance. The pond-culture of carp is an important industry in China and Germany, and has been introduced with some success in the United States, but in England it has long fallen out of use, and is not likely to be revived so long as fresh fish can be obtained and distributed so readily as is now the case. Other examples are to be found in the cisterns of the lagoons of the Adriatic, and of the salt-marshes of various parts of France. Here, as in ancient Greece and Rome, it is the practice to admit young fish from the sea by sluices, into artificial enclosures or "viviers," and to keep them there until they are large enough to be used. An interesting modification of this method of cultivation has been introduced into Denmark. The entrances to the inner lagoons of the Limfjord are naturally blocked against the immigration of flatfish by dense growths of sea-grass (Zostera), although the outer lagoons are annually invaded by large numbers of small plaice from the North Sea. The fishermen of the district consequently combined to defray the expenses of transplanting large numbers of small plaice from the outer waters to the inner lagoons, where they were found to thrive far better than in their natural habitat. The explanation has been shown by Dr Petersen to be due to the abundance of food, coupled with the lack of overcrowding of the small fish. This transplantation of plaice is only repeated for several years with the most successful results, and a suitable subvention to the cost is now an annual charge upon the government funds.

As a result of the international North Sea fishery investigations, it has been proposed to extend the same principle for the development of the deep sea fishery in the neighbourhood of the Dogger Bank. Experiments with labelled plaice, carried out in 1904 by the Marine Biological Association, showed that small plaice transplanted to the Dogger Bank in spring grew three times as rapidly as those grown in the same region, with insignificant variations, has been obtained by similar experiments in each succeeding year. In this case the deep water round the Dogger Bank acts as a barrier to the emigration of the small plaice from the shores. It has consequently been proposed that the small plaice should be transplanted in millions to the Bank by well vessels every spring. It is claimed, as a further result of the experiments, that from May to October the young fish would be practically lost on the shallow part of the Bank from the risk of premature capture by trawlers, and that the increased value of the fish, consequent upon their phenomenon growth-rate, would greatly exceed the cost of the transplantation.

The methods of oyster- and mussel-culture are similar in principle to those just described. A breeding stock is maintained to supply the ground, the "collectors," with spat, and the latter, when sufficient growth is made, then transplanted to the marine feeding-grounds, care being taken to avoid the local over-crowding which is so commonly observed among shell-fish under natural conditions.

Fish-hatching.—That second, and more familiar, type of pisciculture is that known as fish-hatching, with which must be associated the various methods of artificial propagation.

The fertilization of the spawn is very easily effected. The eggs are collected either by "stripping" them from the mature adults immediately after spawning, or by keeping the adults alive until they are ready to spawn, and then stripping them or by keeping them in reservoirs of sea-water and allowing them to spawn of their own accord. In the two former cases a little milt is allowed to fall from a male fish into a vessel containing a small quantity of water—fresh or salt as required—and the eggs are pressed from the female fish into the same vessel. In fresh-water culture the eggs thus fertilized may be at once distributed to the waters to be stocked, or they may be kept in special receptacles provided with a suitable stream of water until the fry are hatched, and then distributed, or again they may be reared in the hatchery for several months until they are ready for sale.

The hatching of fish, whether of fresh-water or salt-water fishes, presents no serious difficulties, if suitable apparatus is employed; but the rearing of fry to an advanced stage, without serious losses, is less easy, and in the case of sea-fishes with pelagic eggs, the larvae of which are exceedingly small and tender, is still an unsolved problem, although recent work, carried out at the Plymouth laboratory of the Marine Biological Association, is at least promising. It has been found possible to grow pure cultures of various diatoms, and by feeding these to delicate larvae kept in sterilised sea-water, great successes have been attained. In fresh-water culture little advantage, if any, has been found to result from artificial hatching, and this is followed by a successful period of rearing. Thus the Howetown Fishery Company recommend their customers to stock their streams either with unhatched ova or with three-month-old fry. Their experience is "that there is no half-way house between ova sown in redds and three-month-old fry. Younger fry may do, but only where ova would do as well, and at half the cost." In marine hatcheries, on the other hand, it is the invariable practice to hatch the eggs, although the fry have to be put into the sea at the most critical period of their lives. If it is a risky matter to plant out the robust young fry of trout under an age of three months, it would seem to be an infinitely more speculative proceeding to plant out the delicate week-old larva of sea-fishes in an environment which teems with predacious enemies.

Objects and Utility of Fish-hatcheries.—The earlier advocates of artificial propagation and fish-hatching seem to have been under the impression that the thousands of fry resulting from a single act of artificial propagation meant a corresponding increase in the numbers of edible fish when once they had been deposited in suitable waters; and also that artificial fertilization ensured a greater proportion of fertilized eggs than the natural process. For the second of these propositions there is no evidence, while the first proposition is now everywhere discredited. It is recognized that the great fertility of fishes is nature's provision to meet a high mortality—greater in sea-fishes with minute pelagic eggs than in fresh-water fishes with larger yolked eggs, partly because of the greater risks of marine pelagic life, and partly because of the greater delicacy of marine larvae at the time of hatching. Artificially propagated eggs and fry after planting must submit to the same mortality as the other eggs and fry around them. Consequently it is useless to plant out eggs or fry unless in numbers sufficiently great to appreciably increase the stock of eggs and fry already existing.

It is this, combined always with the suitability of the external conditions, which accounts for the success of the best experiments of American pisciculturists. The artificially propagated eggs of the shad from the catchets of the United States were planted in those of California and the Mississippi, where the species did not naturally occur. The conditions were suitable, and the species became at once acclimatized. Similarly reservoirs and streams can be stocked with various kinds of fish not previously present. But in the case of indigenous species the breeding stock must be very seriously reduced before the addition of the eggs or fry of a few score or hundreds of fish can appreciably increase the local stock.

In the case of sea-fishes it is becoming increasingly recognized that the millions of cod fry which are annually turned out from our own waters are not a sufficiency, and that our Norwegian hatcheries are but an insignificant fraction of the billion or so eggs naturally produced. A single female cod liberates, according to its size, from one to five million eggs in a single season. Yet the annual output of fry from each of these hatcheries rarely exceeds 200 millions, i.e. the natural product of a few hundred cod at most. In Britain marine hatcheries have been established by the Fishery Board for Scotland in the bay of Nigg, near Aberdeen, by the Lancashire Sea Fisheries Committee at Peel, and by the government of the Isle of Man at Port Erin. These establishments have been principally devoted to the hatching of the eggs of plaice. But again the maximum output of fry from any one of these establishments has not exceeded 300,000 eggs in any single year. As a single female plaice produces about 300,000 eggs per annum, this output does not exceed the natural produce of a few hundred fish. Under these circumstances the probable utility of the operations could be
admitted only if the fry were sedentary and could be planted in suitable localities where young fish were naturally scarce. But the fry drift with the currents as helplessly as the eggs, and the a priori objections to the utility of the operations have in no case been met by evidence of tangible results. The plaece fry hatched in the Scottish establishment have been distributed for many years in the waters of Loch Fyne. Yet in this area, according to the investigations of Mr Williamson (Report of the Scottish Fishery Board for 1898), nearly 500,000 plaece eggs are naturally produced in one spawning season. Evidence is still lacking as to whether the 20 to 30 million fry annually added from the hatchery have appreciably increased the quantities of young plaice on the surrounding shores. Supposing this could be established, the question would still remain whether the same result could not be obtained at far less expense by dispensing with the hatching operations and distributing the eggs directly after fertilization.

In the United States the utility of the cod-hatching operations has been constantly asserted by representatives of the Bureau of Fisheries, but practically the only evidence adduced is the occasional appearance of unusual numbers of cod in the neighbourhood. It has not been established that the fluctuations in the local cod fisheries bear any fixed relation to the extent of the hatching operations, while the earlier reports of the Commissioners of Fisheries contain evidence that similar fluctuations occurred before the hatching of "fish commission cod" had begun.

The situation may be summed up in the words of Mr Fryer, H.M. Superintending Inspector of Fisheries, who critically examined the evidence bearing upon the operations of the Newfoundland Hatchery at Dildo (Reports x., xii., of the Inspectors of Sea Fisheries, E. & W.): "Where the establishment of a hatchery, even on the smallest scale, is followed by an increased take of fish, there is a tendency to connect the two as cause and effect on insufficient evidence, and without any regard to the many conditions which have always led to fluctuations in the case of any particular kind of fish."

The most exact investigations bearing upon this problem are those which have been recently undertaken in Norway in connection with the cod-hatching operations at Arendal under Captain Danneweg. Four fjords were selected in the south coast of Norway in proximity to the hatchery, and the usual number of injections were made into the alternate fjords, leaving the intermediate fjords unaffected. The relative number of young cod in the various fjords was then carefully investigated throughout the succeeding summer and autumn months. It was found that there was no relation between the abundance of young fish and the presence or absence of "artificial" fry. In 1904, 33 million fry were planted in Sondefjord and young fish were exceptionally abundant in the following autumn (three times as abundant in 1903 when no fry were planted). But their abundance was equally striking in other fjords in which no fry had been planted, while in 1905 all the fjords were deficient in young cod whether they had been planted with fry from the hatchery or not.

For a summary of these investigations see papers on "Artificial Fish Hatching in Norway" by Captain Danneweg and Mr Dahl, in the Report of the Lancashire Sea Fisheries Laboratory for 1906 (Liverpool, 1907).

It would thus seem clear that the attempts hitherto made to increase the supply of sea-fish by artificial hatching have been unsuccessful. The experience gained has doubtless not been wasted, but the direction to be taken by future work is plain. The energy and money devoted to hatching operations should be diverted to the serious attempt to discover a means of rearing on a large scale the just-hatched fry of the more sedentary species to a sturdy adolescence. When that has been done (it has been achieved by the present writer in the case of the sea-fish Cottus with demersal eggs,) it would be possible to deposit the young fish in suitable localities on a large scale, with a reasonable prospect of influencing the local abundance of the species of fish in question.

PISCINA—PISIDIA

For further details, see J. T. Cunningham, Natural History of the Marketable Marine Fishes of the British Islands (London, 1865); Memoranda of Fish-Culture (Washington, 1897); Roché, La Chasse des mers (Paris, 1898); W. Garstang, Experiments on the Transplantation of Marketed Plaice (First Report of the North Sea Fisheries Investigation Committee, 1905).

PISCINA, a Latin word first applied to a fish-pond, and later used for any pool of water for bathing, &c., either natural or artificial, and also for a tank or reservoir. In ecclesiastical usage the term was given to a shallow stone basin (the French cuvette) placed near the altar in a church, with drains to take away the water used in the ablutions at the mass. 'Piscinum' seem at first to have been mere cups or small basins, supported on perforated stems, placed close to the wall, and afterwards to have been recessed therein and covered with niche heads, which often contained shelves to serve as aumbries. They are rare in England till the 13th century, after which there is scarcely an altar without one. They frequently take the form of a double niche, with a shaft between the arched heads, which are often filled with elaborate tracing.

PISEK, a town of Bohemia, 55 m. S. of Prague by rail. Pop. (1900), 13,668, mostly Czech. It lies on the right bank of the Wottawa, which is here crossed by an interesting stone bridge of great antiquity. The most prominent buildings are the church of the Nativity, the town-hall, and a castle dating from the 15th century. The industries are iron and brass founding, brewing, and the manufacture of shoes, paper, cement and Turkish fezes. Feldspar, quartz and granite are quarried in the environs. The name of Pisek, which is the Czech for sand, is said to be derived from the gold-washing formerly carried on in the bed of the Wottawa (1571-1621).

In 1619 it was captured by the imperialist general, Karl Bonaventura de Longueval, Graf von Burquoy, and suffered so severely that the citizens opened their gates to his opponent, Ernst von Mansfeld. This was punished in October of the following year, when Duke Maximilian of Bavaria sacked the town and put nearly all the inhabitants to the sword. Pisek was one of the chief centres of the Hussites. It was occupied by the French in 1741.

PISIDIA, in ancient geography, the name given to a country in the south of Asia Minor, immediately north of Pamphylia by which it was separated from the Mediterranean, while it was bounded on the N. by Phrygia, on the E. by Lycaonia, Isauria and Cilicia, and on the W. and S.W. by Lycia and a part of Phrygia. It was a part of Phrygia Lycaonia. It was a very inclement and stunted district, comprising some of the loftiest portions of the great range of Mt Taurus, together with the offshoots of the same chain towards the central table-land of Phrygia. Such a region was naturally occupied from a very early period by wild and lawless races of mountaineers, who were very imperfectly reduced to subjection by the powers that successively established their dominion in Asia Minor. The Pisidians are not mentioned by Herodotus, either among the nations that were subdued by Croesus, or among those that furnished contingents to the army of Xerxes, and the first mention of them in history occurs in the Anabasis of Xenophon, when they furnished a pretext to the Persians for the renewal of their war in Asia. Xenophon was deprived of his life, with his effects, by Perdiccas, to subvert his brother's throne, while he pretended only to put down the Pisidians who were continually harassing the neighbouring nations by their lawless forays (Anab. i. 1, 11: ii. 1, 4, &c.). They are afterwards mentioned frequently by later writers among the inland nations of Asia Minor, and assume a more prominent part in the history of Alexander the Great, to whose march through their country they opposed a determined resistance. In Strabo's time they had passed under the Roman dominion, though still governed by their own petty chiefs and retaining to a considerable extent their predatory habits (giving rise to such wars as that carried on by Quirinius, about A.D. 6 B.C.).

The boundaries of Pisidia, like those of most of the inland provinces or regions of Asia Minor, were not clearly defined, and appear to have fluctuated at different times. This was especially the case on the side of Lydia, where the upland
district of Milyas was sometimes included in Pisidia, at other times assigned to Lycia. Some writers, indeed, considered the Pisidians as the same people with the Milyans, while others regarded them as descendants of the Solymi, but Strabo speaks of the language of the Pisidians as distinct from that of the Solymi, as well as from that of the Lydians. The whole of Pisidia is an elevated region of table-lands or upland valleys in the midst of the ranges of Mt Taurus which descends abruptly on the side of Pamphylia. It contains several small lakes, and two of large size, Bey-Sheker Lake, the ancient Karalis, and the double lake now called the Egerdir Geul, of which the ancient name was Limnai. The latter is a fresh-water lake of about 30 m. in length, situated in the north of Pisidia on the frontier of Phrygia, at an elevation of 3007 ft. Karalis is a larger body, also of fresh water, and at a distinctly higher level above the sea. The only rivers of importance are the Cestrus and the Eurymedon, both of which take their rise in the highest ranges of Mt Taurus, and flow down through deep and narrow valleys to the plain of Pamphylia, which they traverse on their way to the sea.

Notwithstanding its rugged and mountainous character, Pisidia contained in ancient times several considerable towns, the ruins of which have been brought to light by the researches of recent travellers (Arundell, Hamilton, Daniell, G. Hirschfeld, Radet, Sterrett, Lanckoronski, Ramsay, &c.), and show them to have attained under the Roman Empire to a degree of opulence and prosperity far beyond what we should have looked for in a country of predatory mountaineers. The most important of them are Termessus, near the frontier of Lycia, a strong fortress in a position of great natural strength and commanding one of the principal passes into Pamphylia; Cremna, another mountain fortress, north of the preceding, impeding over the valley of the Cestrus; Sagalassus, a little farther north, a large town in a strong position, the ruins of which are among the most remarkable in Asia Minor; Selge, on the right bank of the Eurymedon, surrounded by rugged mountains, notwithstanding which it was in Strabo's time a large and opulent city; and Antioch, known for distinction's sake as Antioch of Pisidia, and celebrated for the visit of St Paul. This was situated in the extreme north-east of the district immediately on the frontier of Phrygia, between Lake Egerdir and the range of the Sultan Dag and was reckoned in the Greek and earlier Roman period, e.g. by Strabo, as a city of Phrygia.

Besides these there were situated in the rugged mountain tract west of the Cestrus Cetepolis, Olbasa, Pogla, Isinda, Etenna and Comama. Pednelissus was in the upper valley of the Eurymedon above Selge. The only place in the district at the present day deserving to be called a town is Isbarta, the residence of a pasha; it stands at the northern foot of the main mass of Mt Taurus, looking over a wide and fertile plain which extends up to the northern chain of Taurus. North of this and immediately on the borders of Phrygia stood Apollonia, called also Mordiaueum. Large estates in Pisidia and the adjoining parts of Phrygia belonged to the Roman emperors; and their administration has been investigated by Ramsay and others.

We have no clue to the ethnic character and relations of the Pisidians, except that we learn from Strabo that they were distinctly Semitic race, but we find mention at an early period in these mountain districts of various other tribes, as the Cabuli, Milyans, &c., of all which, as well as the neighbouring Isaurians and Lycaonians, the origin is wholly unknown, and the absence of monuments of their languages must remain so. A few short Pisidian inscriptions have been published by Ramsay in Revue des études anciennes (1895, pp. 355-362). No inscriptions in these languages are known.

PISTO. the name of a distinguished Roman plebeian family of the Calpurnian gens which continued in existence till the end of the 2nd century A.D. Nearly fifty of its members were prominent in Roman history, but the following deserve particular mention.

1. Lucius Calpurnius Piso Cæsoninus, Roman statesman, was the father-in-law of Julius Caesar. In 58 B.C., when consul, he and his colleague Aulus Gabinius entered into a compact with P. Clodius, with the object of getting Cicero out of the way. Piso's reward was the province of Macedonia, which he administered from 57 to the beginning of 55, when he was recalled, perhaps in consequence of some of his finest performances, by Pompey. On his return Piso addressed the senate in his defence, and Cicero replied with the coarse and exaggerated invective known as In Pisonem. Piso issued a pamphlet by way of rejoinder, and there the matter dropped, Cicero being afraid to bring the father-in-law of Caesar to trial. At the outbreak of the civil war Piso offered his services as mediator, but when Caesar marched upon Rome he left the city by way of protest. He did not, however, definitely declare for Pompey, but remained neutral, without forfeiting the respect of Caesar. After the murder of the dictator he insisted on the provisions of his will being strictly carried out, and for a time opposed Antony. Subsequently, however, he became one of his supporters, and is mentioned as taking part in an embassy to Antony's camp at Mutina with the object of bringing about a reconciliation.

2. Lucius Calpurnius Piso, surnamed Frugi (the worthy), Roman statesman and historian, was tribune in 149 B.C. He is known chiefly for his lex Calpurnia repetundarum, which brought about the system of quedationes perpetuae and a new phase of criminal procedure. As prae tor (136) and consul (133) Piso fought against the slaves in Sicily. He energetically opposed Gaullus Gracchus, especially in connexion with his corn law. See ANNA LI STL: C. Chichors in Pauly-Wissowa's Realencyclo- pädie (1897), vol. iii., pt. 1; H. Peter, Historiarum romanorum reliquiae (1870), vol. i.; Teufell-Schwabe, Hist. of Roman Lit. (Eng. trans.), § 152, 4. On the lex Calpurnia, Corpus inscr. latinorum, l., No. 158. With Mommsen's commentary: A. H. J. Greenidge, Hist. of Rome, 133-190 B.C. (1904).

3. Gnaeus Calpurnius Piso, Roman statesman, was consul in 7 B.C. and subsequently governor of Spain and proconsul of Africa. In A.D. 17 Tiberius appointed him governor of Syria, with secret instructions to thwart Germanicus, to whom the eastern provinces had been assigned. The indignation of the people at the death of Germanicus, and the suspicion that Piso had poisoned him, forced Tiberius to order an investigation. Piso committed suicide, though it was rumoured that Tiberius, fearing incriminating disclosures, had put him to death.

See also: Schiller, Geschichte der römischen Kaiserzeit (1883), vol. i.; Agius Calpurnius Piso, Calpurnius Piso, Roman statesman, orator and patron of literature. Of the 3rd century B.C. He is known chiefly for his share in the conspiracy of A.D. 65 against Nero (q.v.). He was one of the most popular men in Rome, partly for his skill in poetry and music, partly for his love of luxury and generosity.

It is probably the last-named which is referred to by Calpurnius Siculus under the name of Meliboeus, and he is the subject of the panegyric De laude Pisone.

PISSARRO, CAMILLE (1831-1903), French painter, was born at St Thomas in the Danish Antilles, of Jewish parents of Spanish extraction. He went to Paris at the age of twenty, and was at the head of the circle of Cézanne, who produced some of his finest pictures under the direction of the Barbizon masters. Though at first he devoted himself to the study of the kind which will ever be associated with the name of Millet, his interest was entirely absorbed by the landscape, and not by the figures. He subsequently fell under the spell of the rising impressionist movement and threw in his lot with Monet and his friends, who were at that time the butt of public ridicule. Like Monet, he made sunlight, and the effect of sunlight on the objects of nature, the chief subjects of his paintings, whether in the country or on the Paris boulevards. About 1885 he took up the laboriously scientific method of the pointillists, but after a few years of these experiments he returned to a broader and more attractive manner. Indeed, in the closing years of his life he produced some of his finest pictures. Though he dropped down with admirable truth the peculiar atmosphere and colour and teeming life of the boulevards, streets and bridges of Paris and Rouen. He died in Paris in 1903.
Pissarro is represented in the Calilebotte room at the Luxembourg, and in almost every collection of impressionist paintings. A number of his finest works are in the collection of M. Durand-Ruel in Paris.

Pistachio Nut—Pistoia, Synod of

Pistachio Nut, the fruit of Pistacia vera (natural order Anacardiaceae), a small tree which is a native of Syria and generally cultivated in the Mediterranean region. Although a delicious nut and much prized by the Greeks and other Eastern nations, it is not well known in Britain. It is not so large as a hazel nut, but is rather longer and much thinner, and the shell is covered with a somewhat wrinkled skin. It is chiefly produced in Asia Minor and is used by the Turks as a chewing gum. It is also used as a varnish for pictures. P. Terebinthus, the Cypress turpentine tree, a native of southern Europe, Asia Minor and North Africa, yields turpentine from incisions in the trunk. A gall is produced on this tree, which is used in dyeing and tanning.

Pistil, a term in botany for the female or seed-bearing organ of a flower (q.v.). The Lat. pistillum (diminutive from pisum, pistum, to pound), a pestle, a club-headed instrument used for crushing or braying substances in a mortar (q.v.), was taken as the name for this organ from its similarity in shape, and thence adapted in Fr. p?istil about the middle of the 18th century. In its complete form a pistil consists of three parts—ovary, at the base, containing the bodies which become seeds, style, (the slender pillar) and stigma (the sticky summit, or organ, to brand), the part which in impregnation receives the pollen.

Pistoia, or Pistoja (anc. Pistoriae), a town and episcopal see of Tuscany, Italy, in the province of Florence, from which it is 21 m. N.W. by rail. Pop. (1906), 27,127 (town); 68,131 (commune). It is situated on a slight eminence (210 ft.) near the Ombrone, one of the tributaries of the Arno. It is on the site of the Roman Pistoriae, which is hardly mentioned in ancient times, except for the destruction of Catiline’s forces and the slaughter of their leader near it in 62 B.C., and as a station on the road between Florentia and Luca; and earlier still by Plautus, but only with jesting allusion to the similarity of the name to that of the Pistor (lakes). Here is any inscriptions of the ancient town have been found; but excavations in 1903 (see G. Pellegrini in Notizie degli Scavi, 1904, p. 241) in the Piazzale del Duomo led to the discovery of a large private house, which belonged to the end of the 1st century B.C. Some mosaic pavements were found, belonging perhaps to the 3rd century A.D., while the house appears to have fallen into ruin at the beginning of the 5th. Remains of four subsequent periods were discovered above it. It was found that the tradition that the cathedral occupied the site of a temple of Mars was groundless; for the house appears to have extended under it. Ammianus Marcellinus (5th century) mentions Pistoriae as a city of Tuscia Annonaria. During the middle ages Pistoja was at times a dangerous enemy to Florence, and the scene of constant conflicts between the Guelphs and Ghibellines; it was there that the great party struggle took place which resulted in the creation of the Bianchi and Neri factions (see Dante, Inferno, xxiv. 121 to end). In 1302-06 it was besieged and eventually taken by the armies of Florence and Lucca, and in 1325 it became subject to Castruccio of Lucca. In 1357 it was obliged to surrender to Florence, and thenceforth shared its fate.

The city is still surrounded by walls, dating from shortly after the siege of 1302-06; while two inner lines of streets represent two earlier and inner lines of wall. In the early development of architecture and sculpture Pistoia played a very important part; these arts, as they existed in Tuscany before the time of Nicola Pisano, can perhaps be better studied in Pistoia than anywhere else; nor is the city less rich in the later works produced by the school of sculptors founded by Nicola. In the 14th century Pistoia possessed a number of the most skilful artists in silver-work, a wonderful specimen of whose powers exists now in the cathedral—the great silver altar and frontal of St James, originally made for the high altar, but now placed in a chapel on the south side. The cathedral is partly of the 12th century, with a porch and façade with small arcades—in black and white marble, as is the case with several other churches of Pistoia—but was remodelled in the 13th century, and modernized inside in that most tasteful little town with them from Canaan, and in Egypt it is still often placed along with sweetmeats and the like in presents of courtesy. The small nut of Pistacia Lentiscus, not larger than a cherry stone, also comes from Smyrna, Constantinople and Greece. P. Lentiscus is the mastic tree, a native of the Mediterranean region, forming a shrub or small tree with evergreen pinnately-compound leaves with a winged stalk. “Mastic” (from mastikos, to chew) is an aromatic resinous exudation obtained by making incisions in the bark. It is chiefly produced in Asia Minor and is used by the Turks as a chewing gum. It is also used as a varnish for pictures. P. Terebinthus, the Cypress turpentine tree, a native of southern Europe, Asia Minor and North Africa, yields turpentine from incisions in the trunk. A gall is produced on this tree, which is used in dyeing and tanning.

Pistolese, the name of the people of Pistoja.

During the 16th and 17th centuries Pistoja was the scene of acute religious and political strife; in 1571 a .Helmet was thrown in the town by the people against the Archbishop of Pistoja and the conclusion of a peace between the Guelphs and Ghibellines; the latter party was victorious, but the town was taken by the Guelphs in 1577. In 1600 the population of the town was 23,000. During the Napoleonic wars Pistoja was occupied by the Austrians in 1806, and by the French in 1813. The town was captured by the Austrians in 1848, but was recovered by the French in 1859.

In 1870 the national council was held in Pistoja and the national flag of Italy was raised in the town. The town was occupied by the Austrians in 1915, but was recovered by the Italian army in 1918.

Pistoja, Synod of, a diocesan synod held in 786 under the presidency of Scipione de’ Ricci (1741–1810), bishop of Pistoja, and the patronage of Leopold, grand-duke of Tuscany, with a view to preparing the ground for a national council and a reform of the Tuscan Church. On the 26th of January the grand-duke issued a circular letter to the Tuscan bishops suggesting certain reforms, especially in the matter of the restoration of the authority of diocesan synods, the purging of the missals and breviaries of legends, the assertion of episcopal as against papal authority, the curtailing of the privileges of the monastic orders, and the better education of the clergy.
In spite of the hostile attitude of the great majority of the bishops, Bishop de' Ricci issued on the 31st of July a summons to a diocesan synod, which was solemnly opened on the 18th of September. It was attended by 233 beneficed secular and 13 regular priests, and decided with practical unanimity on a series of decrees which, had it been possible to carry them into effect, would have involved a drastic reform of the Church on the lines advocated by *Febronius* (see *FERRONIANS*).

The first decree (Decretum de fide et ecclesia) declared that the Catholic Church has no right to introduce new dogmas, but only to preserve in its original purity the faith once delivered by Christ to His apostles, and is infallible only so far as it conforms to Holy Scripture and true tradition; the Church, moreover, is a purely spiritual body and has no authority in things secular. Other decrees denounced the abuse of indulgences, of festivals of saints, and of processions and suggested reforms; others again enjoined the closing of shops on Sunday during divine service, the issue of service-books with parallel translations in the vernacular, and recommended the abolition of all monastic orders except that of St Benedict, the rules of which were to be brought into harmony with modern ideas; nuns were to be forbidden to take the vows before the age of 40. The last decree proposed the convocation of a national council.

These decrees were issued together with a pastoral letter of Bishop de' Ricci, and were warmly approved by the grand-duke, at whose instance a national synod of the Tuscan bishops met at Florence on the 23rd of April 1787. The temper of this assembly was, however, wholly different. The bishops refused to allow a voice to any not of their own order, and in the end the decrees of Pistoia were supported by a majority of only three. They were finally condemned at Rome by the bull *Auctorem fidei* of the 28th of August 1794. De' Ricci, deprived of the personal support of the grand-duke (now the emperor Leopold I.), exposed to pressure from Rome, and threatened with mob violence as a suspected destroyer of holy relics, resigned his see in 1791, and lived in Florence as a private gentleman until his death in 1810. In May 1805, on the return of Pope Pius VII. from Paris, he had signed an act of submission to the papal decision of 1794.

De' Ricci's own memoirs, *Memorie di Scipione de' Ricci, residen di Prato e Pistoia*, edited by Antonio Galli, were published at Florence in 2 vols. in 1865. Besides this his letters to Antonio Marini were published by Cesare Guasti at Prato in 1857; these were promptly put on the Index. See also De Potter, *Vie de Scipione de' Ricci* (3 vols, Brussels, 1825), based on a MS. life and a MS. account of the synod placed on the Index in 1825. There are many documents in Zobi, *Storia civile della Toscana*, vols. ii. and iii. (Florence, 1856). The acts of the synod of Pistoia were published in Italian and Latin at Pavia in 1798.

**PISTOL**, a small fire-arm designed for quick work and personal protection at close quarters, and for use in one hand. It was originally made as a single and also double-barrelled smooth bore muzzle-loader, involving no departure in principle from the ordinary fire-arms of the day. With the introduction of revolvers and breech-loading pistols and the application of "rifling" to musket barrels, came also, in the early half of the 19th century, the rifling of pistol-barrels.

**History.**—Pistols are understood to have been made for the first time at Pistoia in Italy, whence they receive their name. Caminello Vitelli, who flourished in 1540, is the accredited inventor. The first pistols, in the 16th century, had short single barrels and heavy butts, nearly at right angles to the barrel. Shortly afterwards the pattern changed, the butts being lengthened out almost in a line with the barrels. These early pistols were usually fitted with the wheel-lock (see *Gun*). Short, heavy pistols, called "daggs," were in common use about the middle of the 17th century, with butts of ivory, bone, hard wood or metal. A chiselled Italian dagg of 1650, for example, had a slightly bell-nosed barrel of about 8 in. in length and 14 bore. The German wheel-lock military pistols used by the Reiters, and those made for nobles and gentlemen, were profusely and beautifully ornamented. Pistols with metal butts were common in the 16th and 17th centuries; many beautiful specimens of which, silver-mounted, were made in Edinburgh and used by Highlanders. Duelling, when in vogue, caused the production of specially accurate and well-made single-barrelled pistols, reliable at twenty paces. The pattern of this pistol seldom varied, its accuracy at short range equalling that of more modern ones; the principle of a heavy bullet and light charge of powder being employed. The first double-barrelled pistols were very bulky weapons made with the barrels laid alongside one another, necessitating two locks and two hammers. There was also the "over and under" pistol, one barrel being laid over the other. This was a more portable weapon, only requiring one lock and hammer, the second barrel being turned round by hand, after the first had been fired, or, as an alternative, the flash-hole being adjusted to the second barrel by a key. These pistols were first made with flint and steel locks and subsequently for percussion caps. Double "over and under" pistols were also made with a trigger mechanism that served to discharge both barrels in turn.

**Revolvers.**—A revolver is a single-barrelled pistol with a revolving breech containing several chambers for the cartridges, thus enabling successive shots to be rapidly fired from the same weapon without reloading. The ordinary pistol is now, and has been for many years past, superseded by the revolver. The first revolver, fired with the percussion cap, was made with the whole of the barrels, six, seven or eight, revolving in one piece, and was known as the "pepper-box." It was "single action," i.e. the hammer was raised and the barrels revolved by the pull of the trigger. This weapon was cumbersome and no accurate aim could be taken with it owing chiefly to the strength and resistance of the main-spring and the consequent strong pull required on the trigger. The principle of a revolving breech to one barrel, which superseded the "pepper-box," is an old one in the history of fire-arms, dating from the 16th century. At first the breech cylinder was revolved by hand, as in the revolving arquebus or matchlock, a specimen of which is now in the

---

PISTOL

Tower of London, but this was subsequently improved by introducing geared mechanism, by which the pull of the trigger or the cocking of the hammer, or both, do the work. There exists a pistol of the time of Charles I. which is rotated automatically as the hammer is raised.

In 1814 a self-acting revolver mechanism of a crude pattern was produced in England. Four years later Collier used a separate spring to rotate the chamber. In 1835, an American, Samuel Colt, produced and patented the first practical revolving pistol, the idea of which was obtained by him, it is stated, from an ancient "revolving" weapon in the Tower of London. The chambers of the first Colt revolver were loaded with powder and bullets from the muzzle end, and each chamber had a nipple that required to be capped. It was the invention of the copper cap that made the Colt revolver possible. Under the old priming system with exposed powder in a pan the difficulty of separate and effective ignition with the revolving cylinder was almost insuperable.

The first American revolver makers caused the cocking of the hammer to revolve the cylinder, while the English makers effected this by the pull of the trigger. In 1855, Adams of London, and also Tranter of Birmingham, brought out the double-action revolver, in which the revolution of the cylinder could be effected by both these methods. When the revolver is cocked and fired by pressing the trigger, greater rapidity of fire is obtained than when the hammer is cocked with the thumb, but accuracy is impaired, as the trigger requires a long pull and considerable force in order to compress the mainspring and revolve the cylinder. The double action revolver was, therefore, a great advance on the single action, enabling the first and also following shots, if desired, to be accurately fired by a moderate pressure of the trigger after the hammer had been cocked by the thumb; or, alternatively, the revolver could be forward on the frame of the pistol. The extractor, being fast to the pivot, retained the cartridges until the chamber was pushed clear of them. Then the chamber was made to swing on one side, as in the Colt pistol illustrated, enabling all the cartridges to be simultaneously extracted. Finally, self-extracting revolvers with jointed frames were introduced, in which the dropping of the barrel forces out the extractor as in an ordinary double gun, the extractor acting simultaneously in all the chambers of rapidly fired, if necessary, by the trigger action alone. Many revolvers on the Colt principle were in use during the Crimean War and the Indian Mutiny, and proved of valuable service to British officers.

As rim-fire, pin-fire and central-fire cartridges were success-
PISTOL

The pistol. A spring returns the extractor to its place when the empty cartridge cases have been ejected, and brings the barrel to an angle of about 45°, for convenience in loading. The soundness and rigidity of the weapon depend upon the efficiency of the connexion between the barrels and the standing breech, and a top snap bolt has proved the strongest and handiest with the pistol, as with the shot-gun.

This type of revolver originated with Messrs Smith & Wesson, and they and other gunmakers have greatly improved upon the original model. Between the American pattern and the English, as made by Messrs F. Webley & Son, the chief difference is that in the Smith & Wesson the holding-down bolt or catch is upon the barrel, and it engages with the top of the standing breech; whereas in the Webley the bolt is upon the standing breech and grips the extremity of the hinged barrel. Neither mechanism is as strong as could be wished if heavy charges of smokeless nitro-compounds are to be used. This hinged type of revolver is most convenient for use on horseback, as the pistol can be opened, the cartridges extracted and the weapon reloaded with one hand.

The Colt's Double-action Revolver, caliber .38, model 1869, used in the United States army, consists (figs. 7 and 8) of the barrel (B), the cylinder (C) with six chambers, the frame (F), and the firing mechanism, all of steel. The muzzle velocity, with a charge of 16 grains of black powder and a bullet of 150 grains of lead, is about 700 ft. per second, giving at 25 yards a penetration of about 3 in. in pine.

The lock mechanism consists of the hammer (h), with its stirrup (r), stirrup pin (p), strut (s), strut pin (i), strut spring (g); the trigger (t), the rebound lever (l), the hand (a), with the bolt (c), the cylinder bolt (b), with its spring (s); the locking lever (e), the main spring (m), and rebound lever spring (n). The hammer (h), trigger (t), and rebound lever (l) are pivoted on their respective pins, which are fastened in the left side of the frame. The lower end of the rebound lever spring (n) is secured to the frame and the free end bears under the rear end of the rebound lever so that the latter, when the trigger is released, cams the hammer back to its safety position, and forces the trigger forward. Pressure upon the trigger causes its upper edge to engage the strut, and thereby raises the hammer until nearly in the full-cock position, when the strut will escape from the trigger, and the hammer, under the action of the main-spring, will fall and strike the cartridge. A projection on the upper part of the trigger, working in a slot in the frame, prevents the cylinder from making more than one-sixth of a revolution at a time by entering one of the grooves nearest the rear end of the surface of the cylinder. When the cylinder is swung out of the frame, the parts are arranged to prevent the cocking of the hammer. The cylinder bolt is pivoted on the trigger pin, and its spring, bearing on the rebound lever arm, causes the nose of the bolt to project through a slot in the frame ready to enter one of the rectangular cuts in the cylinder surface. During the first movement of the trigger in cocking the revolver, the nose of the bolt is withdrawn, allowing free rotation of the cylinder. The object of the bolt is to prevent rotation of the cylinder in transportation. The hand is attached by its pivot to the trigger, and, as the latter swings on its pin when the hammer is being cocked, the hand is raised and revolves the cylinder, and also serves to lock the cylinder in position at the time of firing. An abutment on the side plate supports the hand spring in rear. The spring ensures the engagement of the hand with the ratchet (q). The revolver is cocked by hand by withdrawing the hammer by the pressure of the thumb until its full-cock notch engages in the rear sharp corner of the trigger. Pulling the trigger then releases the hammer, allowing its firing pin (f), to move forward and strike the cartridge.

The locking lever is pivoted by its screw in a recess in the left side of the frame, and so connected with the latch that it locks the hammer and trigger when the latch is pushed to the rear for opening the cylinder, and does not unlock them until the cylinder is positively closed and is locked by the latch. The cylinder revolves and is supported on a central arbour of the crane (E). The crane fits in a recess in the frame below the barrel and turns on its pivot arm (A). The ejector rod with its spring passes through the centre of the cylinder arbour and is terminated in rear by the ejector with a ratchet (y). Pushing against the front end of the ejector rod will empty the chambers, the cylinder being swung out for loading. The thumb-piece of the latch (l) slides to the rear in the left side of the frame, unlocking the cylinder for opening, but upon closing the cylinder, the body of the latch firmly enters a recess in the ejector, locking the cylinder in position for firing.

One great disadvantage of revolvers is the escape of gas at the opening between the breech of the barrel and the cylinder.

FIG. 5.—Percussion-lock pistol (Royal United Service Institution).

This escape corrodes the surrounding parts and also materially diminishes the pressure in the barrel and the consequent velocity of the bullet. In the Nagant revolver, adopted by Russia, this disadvantage has been overcome by employing a long cartridge case which extends beyond the nose of the bullet and bridges the gap between barrel and cylinder as the cylinder is moved forward. A "mitrailleur" pistol has also been constructed by the Braendlin Armoury Co., Ltd., on the "pepper-box" principle, with fixed barrels, either four or six, arranged in pairs, and a special striking mechanism, in which there is no revolving chamber and no escape of gas at the breech. It gives stronger shooting than a revolver, but is more cumbersome, and has the serious defect that the shock of the discharge of one barrel sometimes prematurely fires a second barrel.

In 1865, Sharp, an American, patented an invention to remedy the escape of gas, in which the four barrels of the pistol were drilled the full length out of one block of metal. The barrels are slid forward by an under lever to load, and the firing was effected by a revolving head to the hammer, set by the action of cocking the pistol.

About 1875 Messrs Lancaster introduced both two- and four-barrelled hammerless pistols, in which an internal hammer was worked by the pull of the trigger. In all the three weapons...
above mentioned, extraction and reloading were slow processes, which made them unsuited for use on horseback.

Hammerless Revolver.—The Smith & Wesson pocket pistol is one of the safest weapons of the size made. There is no hammer or equivalent protuberance to catch as the pistol is drawn from the pocket; or to entangle if the weapon falls. An automatic safety bolt, whose length lies half across the palm of the hand, and ensures certainty of freedom at the time of shooting, blocks the action until the pistol is firmly gripped for use.

Breec-h-loading Pistols.—Although the revolver has for many years practically superseded the pistol, some breech-loading varieties of pistols are still made—the small pocket pistol, for example, and occasionally the heavy double-barrelled horse pistol. At one time these latter were much used, of .577 bore, as well as the well-known short, large-bore pistol known as the Derringer, usually of .41 calibre. The double horse pistol is now usually made for a 20-bore cartridge and spherical bullet, and weighs about 3½ lb. It is a clumsy, but effective weapon, and fires a charge of 1½ drams of powder without unpleasant recoil. The dwelling pistol, as made by Garton Renette of Paris, is capable of wonderfully accurate shooting, firing a 9 millimetre spherical bullet and about 12 grs. of powder. This

Hammerless Revolver. The Smith & Wesson pocket pistol is one of the safest weapons of the size made. There is no hammer or equivalent protuberance to catch as the pistol is drawn from the pocket; or to entangle if the weapon falls. An automatic safety bolt, whose length lies half across the palm of the hand, and ensures certainty of freedom at the time of shooting, blocks the action until the pistol is firmly gripped for use.

Automatic Revolver.—The Webley-Fosbery automatic revolver is a weapon of a distinctly new design, in which for the first time the principle of utilizing the recoil of each shot to operate the mechanism is applied to the revolver. In appearance the weapon is very similar to the Webley service model. The simple pressure of the forefinger on the trigger, the pressure being released between each shot, is all that is required to fire the six successive shots of the revolver. It is supplied with a safety bolt worked by a thumb-piece, and Messrs. Webley have introduced a clip loader which enables the six chambers to be reloaded at the same time. This weapon has met with considerable success, and is made in two calibres, the .455, 6 shot, 2 lb 3½ oz. in weight; and the .38 model, 8 shot, 2 lb 3 oz. in weight.

Automatic Pistols.—These weapons are the latest and most advanced type of pistol, and it is anticipated by experts that they will ultimately supersede the revolver. They are made with one barrel and a magazine, on the principle of the repeating rifle, thus doing away with the escape of gas that takes place in revolvers between the chamber and the barrel.

Automatic pistols are so constructed that the force of the recoil is utilized to open the breech, extract the empty case, cock the pistol, reload the chamber with the top cartridge from the magazine, and close the breech, leaving the pistol ready to fire on again pressing the trigger.

The Mauser "self-loading" pistol (fig. 9) is one of the earliest of the successful automatic weapons. It is usually .300 calibre, 10 shot, with a metal clip loader from which the cartridges are "striped" into the magazine, weight 2½ lb, length of barrel 5½ in.; bullet 85 grains, initial velocity about 1394 f.s.

The barrel (1) and bôd (2) are in one piece; the latter contains the bolt (3). The barrel and body slide on the frame (4); the 10-shot magazine (5) and the stock are in one piece with the frame, and the lock frame (6) and lock-work are contained in the rear part of it. The bolt (3), which is square, slides in the body, and is kept pressed up to the chamber by the bolt spring (8); the rear end of this bolt spring bears against the block (9). The striker and extractor are contained in the bolt. The bolt is locked by the bolt-lock (10). This is slotted through the centre, and fits on the projection (11) under the body; it is supported at the moment of firing by a projection on the lock frame (12); the top of the bolt-lock has two teeth (13), which in the loaded and cocked position fit into the slots in the bottom of the front end (in front of the body attachment (11)) has another tooth (14) which bears on the rocker (15). This rocker is pivoted at its bottom corner. The main-spring (16) bears in front against the rocker, and in rear against the hammer mechanism. The action of the mechanism is
PISTOL

as follows: On pressing the trigger, the trigger nose lifts the lever (18) which is attached to the sear (19), the lifting of the sear allows the main-spring to act backwards on the hammer, which impinges on the striker and causes the cartridge to be fired. At this moment the bolt is locked by the two upper teeth (13) of the bolt-lock, which is itself held up by the lock frame projection (13). But, the barrel body and bolt recoiling together (8) of an in., the rear end of the bolt-lock is no longer supported, the rocker (15) acting on the forward tooth (14) pulls down the bolt-lock and its upper teeth, the nose of the bolt-lock falling into the recess just behind the projection (12). Thus the barrel and body come to a standstill and the remaining recoil energy is used in driving back the bolt (now free) and extracting the cartridge case. When this energy is used up the bolt spring (8) reasserts itself, drives the bolt forward and pushes another cartridge into the chamber as in the magazine. But, the main-spring, acting on the rocker, pulls up the bolt-lock again and engages the teeth (13) in the bolt, locking it for the next shot. The releasing of the trigger brings the sear (19) to its former position, cocking the pistol.

This pistol is usually supplied with a wooden holster which can also be attached to the grip of the pistol and so forms a stock for long-range shooting. It is sighted from 50 to 1000 yards.

The Colt Automatic Pistol, calibre .38 (fig. 10) consists of four main parts: namely the frame (F), the barrel (B), and the magazine (M). The frame forms, at its rear and lower part, the handle (A), which is hollow, and contains the seat for the magazine. After being charged with seven cartridges, the magazine is seated from below and held in place by the magazine catch (e) which slightly projects from the bottom of the handle. This projection serves to release the magazine from the catch, when it can be readily drawn from the handle for re-charging. In front of the handle is the trigger guard (g), in which the trigger (d) is found, and in the rear and above the grip the firing mechanism is placed in the part of the frame called the receiver (K). The firing mechanism consists of the hammer (h), the sear (e), the trigger (d), a selector which selects the spring (r) and sear spring (c), the lower part of the latter serving to operate the magazine catch. The top of the receiver extends forward from the handle, and to it the barrel is attached by two short links, (f) near the front end of the barrel, and the other (o) at its rear end; these links are pivoted to the receiver and also to the barrel, and allow the barrel to swing forwards thereon. As both links are of the same length, the rearward movement of the barrel in swinging on these links carries the barrel slightly downwards, but keeps its longitudinal axis in parallel positions during all its movements. Below the barrel the receiver forms a tubular seat for the retractor spring (r), which in front is closed by a plug (e) fastened in the receiver by the lower pivot-pin (I) of the front barrel-link. The upper surface of the receiver and the two longitudinal grooves on its sides form the seat for the slide, which is guided therein in its rearward and forward movements. The rear part of the slide forms the breech block (K), and the front part forms a partly tubular cover (s) which encloses the barrel. In the forward part of the receiver is a transverse mortice extending through the retractor spring seat, and transverse mortices in the forward part of the slide serve to admit a key (m) which, passing through the sides of the slide and through the mortice, serves to lock the slide to the frame. The retractor spring (r), in the frame consists of a spiral spring, the rear end of which rests against the receiver, and the front end of which carries a piston (p). The rear face of the key (m) has a slight recess, and when the key is in its place the front end of the retractor spring is forced by the key, thereby forcing the barrel to retract. The tension of the retractor spring is exerted to force the key and the slide to their forward position. Upon the barrel are three transverse ribs (b), and in the interior of the slide are three corresponding recesses. These serve to lock the breech block and the slide firmly together when in their forward position. Between the locking recesses and the bolt, the slide has an opening on its right side for the ejection of the cartridge cases (j), and the bolt is provided with an extractor, a firing pin (f), and a firing pin retraction spring (g), and a firing pin lock (y). This latter is pivoted at the rear end in the top of the slide, and when depressed, locks the firing pin in its retracted position, thus preventing its point from coming in contact with the cartridge primer. When raised, the firing pin lock releases the firing pin, and in this position also serves as the rear sight, being provided on the top with a sighting notch.

The operation of the pistol is as follows: When a charged magazine (M) is inserted, the slide (S) is drawn once to the rear by hand, thereby cocking the hammer (h). In this position of the slide, the carrier (c) and carrier spring in the magazine raise the retractor spring so as to bring it into the path of the bolt (K). On releasing the slide, it, with the bolt, is carried forward by the retractor spring (r), and during this movement the bolt forces the topmost cartridge into the barrel (B). As the slide approaches its forward position the front of the bolt encounters the rear end of the barrel and forces the latter to its forward position. During this forward movement the barrel swings forward and upward on the links (f, o), and thus the locking ribs (b) on the barrel are carried into the corresponding recesses in the slide. The barrel and slide are thereby interlocked, and the pistol ready for firing.

A slight pull on the trigger (d) now serves to move the sear (e) so as to release the hammer (h) and fire. The forcible of the powder gases driving the bullet from the barrel is exerted rearwardly against the bolt, and, overcoming the inertia of the slide and the tension of the retractor spring, causes the slide and the barrel to recoil together. After moving rearwards together, for a distance, enough to ensure the bullet having passed from the barrel, the downward swinging movement of the barrel releases the latter from the slide and stops the barrel in its rearmost position. The rearward movement of the slide, caused by the retractor spring, causes the slide, in which the carriage is driven into the barrel, and the slide and barrel are interlocked, thus making the pistol ready for another shot. These operations may be continued so long as there are cartridges in the magazine, each discharge requiring only the slight pull on the trigger. The pistol is provided with a safety device (a) which makes it impossible to release the hammer unless the slide and barrel are in their first forward position and interlocked.

In the Borchardt-Leuger pistol (fig. 11) the bolt is solidly supported at the moment of firing by a toggle joint. The barrel (1 A) and body (B) slide in the frame (C), the bolt (2) slides in the body and is held up to the breech by the toggle joint 3 and 4 and the pins 5 and 7, which secure the links of the toggle to the body. The centre of pin (6) is below those of the other pins so that the joint cannot bend at the moment of firing. On the rear link (4) there is a swivel (q) which is connected to the recoil spring (10) in the grip. This pistol is fired by a spring striker, like a rifle, instead of by a hammer. The striker is within the bolt; it is cocked in the recoil position by a claw on the end of the front link (3 A) and held thus when ready to fire by the nose of the trigger seat, these engaging with a projection (8) on the side of the striker. The magazine (8 shot) is in the grip. The action is as follows: the first cartridge is loaded from the magazine by pulling back the toggle joint. As soon as the toggle joint is released the recoil spring acts and forces the bolt home, with the cartridge in front of it. On pressing the trigger the barrel and body recoil a little. Then the toggle joint comes
against curved ramps on the sides of the non-recoiling frame and is forced up, so that thereafter the bolt alone recoils (the ejector is similar in principle to that of a rifle). The recoil spring then acts as before on reloading.

Other varieties of the automatic pistol are the "Mannlicher," the "Mars," the "Bergmann" and the "Webley." The last, being simple in construction, small and light, weight 18 oz. and length over all only 6½ in., may be classed as a pocket pistol.

Qualities of Automatic Pistols.—In reference to the general qualities of automatic pistols, while these weapons have the advantage over revolvers of longer range and greater rapidity of fire and recharging, on the other hand they are necessarily more complicated in their mechanism, which has to do the work of both reloading and cocking that in the revolver is done by hand. A stoppage may occur through the cartridge missing fire, or continuous uncontrolled fire may take place through the trigger spring breaking until the magazine is exhausted. Their action is also to some extent uncertain, as it depends on the recoil of the discharge, which may be affected by variables in the cartridge; also the effective automatic working of the moving parts depends upon their cleanliness and lubrication. As automatic pistols, like revolvers, are intended for personal defence at short range and for sudden use in emergencies, simplicity of mechanism and certainty of action are in their case of paramount importance. There is usually no time to rectify a screw or a mechanism, however slight. From all these points of view, therefore, before the revolver is altogether superseded by the automatic pistol, it is most desirable that the latter should be as certain in its action under service conditions as the former. Some automatic pistols, as already stated, are sighted up to 1000 yards, and provided with attachable butts. The practical value of these improvements is open to question, as the sighting of a pistol differs materially when used with and without a butt, and under no circumstances can the accuracy of shooting of a pistol, even with a butt, equal that of a carbine.

The tendency in automatic pistols has been to reduce the bore to .3 in., and increase the muzzle velocity, on the lines of modern small arms. And, while this, again, would appear to be advantages of minor importance in a weapon intended for use at short range in the field, where a heavy bullet of fairly large diameter, with a moderate muzzle velocity, has a more immediate and paralysing effect, and is therefore, from this point of view, and particularly in savage warfare, preferable to a small projectile of high muzzle velocity.

PISTOLE, the French name given to a Spanish gold coin in use from 1537; it was a double escudo, the gold unit, and was worth 16s. 11d. sterling. The name was also given to the louis d'or of Louis XIII. of France, and to other European gold coins of about the value of the Spanish coin.

PISTON (through Fr. from Ital. pistone or pietone, a great pestle, from Late Lat. pistrone, to pound, a connotative form of classical Lat. pīsome), in the steam engine, a disk or partition placed inside the cylinder, from end to end of which it moves alternately under the pressure of the steam. By means of the "piston-rod" attached to it this forward and backward motion is communicated to the machinery which the engine is employed to drive, and is in most cases converted into rotary motion by a "connecting-rod," one end of which is joined to the "cross-head" carried at the end of the piston-rod, while the other turns the crank on the crank-shaft. The piston in gas, oil and air engines has a similar function, but in a pump, instead of imparting motion, it has motion imparted to it by some prime-mover. In every case the piston must fit the cylinder so accurately that as little as possible of the working fluid, whether it be steam, gas or water, can escape past it, packing of various forms being commonly placed round its periphery in order to secure this fit. In music, the valves which in certain wind instruments, such as the cornet, enable the player to increase the length of the air-column and thus lower the note produced, are known as pistons. (See VALVES.)

PIT (O. E. pyt, cognate with Du. pel, Ger. Fütte, &c., all ultimately adaptations of Lat. puteus, well, formed from root ṭe-, to cleanse, whence purus, clean, pure), a term of wide application for a hole, cavity or excavation in the earth or other surface; thus it is applied to the excavations made in the ground for the purpose of extracting minerals, e.g. chalk, gravel or sand, or for carrying on some industry, e.g. tin-pit, salt-pit, or to the group of shafts which form a coal-mine. Roots and other vegetables can be stored in the winter in a pit, and the term is thus transformed to a heap of such vegetables covered with earth or straw. The word is also used of any hollow or depression in a surface, as in the body, the arm-pit, the pit of the stomach, or on the skin, as the scars left by small-pox or chicken-pox. As applied to a portion of a building or construction, the word first appears for an enclosure, often sunk in the ground, in which cock-fighting was carried on, a "cock-pit." It would seem a transference of this usage that gave the common name to that particular form of cockpit in which birds are trained to fight. Outside this form, the French pâtre. In the United States a special usage is that of its application to that part of the floor space in an exchange where a particular branch of business is transacted; thus in the Chicago Board of Trade, transactions in the grain trade are carried on in what is known as the "Wheat Pit." In Scottish legal history there was a baronial privilege which in Latin is termed furca et fossa, "fork (i.e. gallows) and pit"; where the term has usually been taken to refer to the drowning-pit, in which women criminals were put to death; others take it to refer to an ordal pit. There is a parallel phrase in M. Dutch, putte ends goigen; here putte is the pit in which women were buried alive as a form of punishment.

PITCAIRN, an island in the mid-eastern Pacific Ocean, in 25° 3' S., 130° 6' W., belonging to Great Britain. It lies south of the Paumotu archipelago, 100 m. from the nearest member of this group. Unlike the majority of the islands in this region, it is without coral reefs, but rises abruptly with steep and rugged cliffs of dark basaltic lava. The extreme elevation is over 2000 ft., and the area 2 sq. m. The soil in the valleys is volcanic and fertile, but the gradual utilization of natural timber increases the liability to drought, as there are no streams. The climate is variable and rainy. Stone axes, remains of carved stone pillars similar to those of Easter Island, and skeletons with a pearl-mussel beneath the head have been found in the island, though it was uninhabited when discovered by Philip Carteret in 1767. Pitcairn was the name of the midshipman who first observed it.

The island was destined to become the scene of a curious social experiment. On the 28th of April 1780 a mutiny broke out on board the "Bounty," then employed by the British government in conveying young bread-fruit trees from Tahiti to the West Indies. The commander, Lieutenant William Bligh, was set adrift in the launch with part of the crew, but managed to make his way to Timor in the Malay Archipelago. The twenty-five mutineers at first all returned to Tahiti. Some of them eventually left Tahiti and made their way to England, three being executed in 1792. Meanwhile in 1790 a party consisting of Fletcher Christian, the leader of the mutiny, eight Englishmen, six Polynesian men and twelve Polynesian women had taken possession of Pitcairn Island and burned the "Bounty." Treachery and debauchery filled the first years of the annals of the beautiful island. By 1800 all the men were dead except Alexander Smith, afterwards known as John Adams, who rose to a sense of his responsibility and successfully trained up the youthful generation left in his charge. An American vessel, the "Topaze," discovered the strange colony in 1808; again, by accident, it was visited by the "Britten," Captain Sir F. Staines, and the "Tagus," Captain Picon, in 1817; and by the exploring ship "Blossom" in 1825. On the death of John Adams on the 29th of March 1829 George Hunn Nobbs, who had settled at Pitcairn in 1828, was appointed pastor and chief magistrate. Through fear of drought the islanders removed to Tahiti in 1830, but disproved of both the climate and the morals of this island, and returned to Pitcairn in 1831. Shortly after this an adventurer named Joshua Hill appeared, and, claiming government authority, tyrannized over the islanders till his removal by a British man-of-war in 1858. In 1856 the whole of the islanders—60 married persons and 134 young men, women and children—were landed on
PITCAIRNE, A.—PITCH, MUSICAL.

Norfolk Island, but in 1852 two families chose to return, and their example was afterwards followed by a few others. Visited in 1873 and 1878 the colony was found in excellent order, but by the end of the century it was stated that intermarriage was bringing a deterioration of intellect, morals and energy, and that the islanders would probably drift into imbecility. Later accounts made it appear that this was an exaggeration, although the standard of morality was unquestionably low on the whole.

In religion the islanders are Seventh Day Adventists. "They have adopted an extraordinary pantheon, derived from the language of the Tongans. Women who accompanied the mutineers of the "Bounty" to Pitcairn Island, although most of the islanders who can speak the English language fairly well" (R. T. Simons, Report, 1905). The island is a British colony by settlement, and is within the jurisdiction of the High Commissioner for the Western Pacific (since 1898). There is a governing body chosen from among the islanders, the constitution of which has been altered more than once owing to internal jealousies, &c. The island produces sweet potatoes, yams, melons, bananas and other fruits, arrowroot and coffee. Goats and chickens run wild. Some trade is carried on with Mangareva in a vessel owned by the islanders. The population is about 300.

Pitcairne. Archibald (1652-1713), Scottish physician, was born at Edinburgh on the 25th of December 1652. After obtaining some classical education at the school of Dalkeith, Pitcairne entered Edinburgh University in 1668, and took his degree of M.A. in 1671. Having been sent to France for the benefit of his health, he was induced at Paris to begin the study of medicine, and after courses at Edinburgh and Paris he obtained in 1680 the degree of M.D. at Rheims. He began practice at Edinburgh, and in a short time acquired so great a reputation that in 1692 he was appointed professor of medicine at Leiden. Among his pupils were Richard Mead and H. Boerhaave, and both of them contributed much of their skill to the benefit of their pupil. Pitcairne returned from Paris to Edinburgh in 1693, and in 1695 he returned to Scotland to marry a daughter of Sir Archibald Stevenson, an eminent physician in Edinburgh. The family objected to her going abroad, so he did not return to Leiden, but settled once more in Edinburgh. He rose to be the first physician in Scotland, and was frequently called into consultation both in England and Holland. Soon after his return to Edinburgh, feeling the great want of the means of anatomical study, he imported the town council to permit himself and certain of his medical friends to treat without fee the sick paupers in "Paul’s Work," on condition of being allowed to dissect such of the bodies as were unclaimed by their relatives, and therefore had not been buried at the town’s expense. Strongly enough this proposal was strongly opposed by the chief surgeons of the place, but ultimately the town council had the good sense to comply with Pitcairne’s request, and in this way he may be said to have the credit of laying the foundation of the great Edinburgh school of medicine.

Pitcairne’s medical opinions are chiefly contained in a volume of Dissertations medicæ which he published in 1701 (2nd ed. 1713). In these he discusses the application of geometry to physics, the circulation of the blood in the smaller vessels, the difference in the quantity of the blood contained in the lungs of animals in the womb and of the same animals after birth, the motions by which food becomes fit to supply the blood, the question as to inventors in medicine (in which he repels the idea of certain medical discoveries of modern times having been known to the ancients, especially vindicating for Harvey the discovery of the circulation of the blood, and refuting the view that it was known to Hippocrates), the cure of fevers by evacuating medicines, and the effects of acids and alkalis in medicine. Pitcairne was a good classical scholar, and wrote Latin verses, occasionally with something more than mere imitative cleverness and skill. He was supposed to be the author of a comedy, The Assembly, or Scotch Reformation, and of a satirical poem (black of which was printed in Great Britain and America. The picture of the divines of the time, whom, as a loudly avowed Jacobite, he strongly disliked. He was prone to irreverent and ribald jests, and thus gained the reputation of being an unbeliever and an atheist, though he was a professed deist. The stories about his over-indulgence in drink are probably exaggerated. He was repeatedly involved in violent quarrels with his medical brethren and others, and once or twice got into scrapes with the government on account of his indiscreet political utterances. Among his friends, however, he was evidently well liked, and he is known to have acted with great kindness and generosity to deserving men who needed his help. Thomas Ruddiman, the Scottish scholar, for example, was rescued from a life of obscurity by his encouragement and assistance, and by no one was his memory more gratefully cherished. Mead, too, appears never to have forgotten what he owed to his old teacher at Leiden. A son of Pitcairne’s had gone out in the rebellion of 1715, and, having been condemned to death, was saved by the earnest intercession of Mead with Sir Robert Walpole. He pleaded, very artfully, that if Walpole’s health had been bettered by his skill, or if members of the royal family were preserved by his care, it was owing to the instruction he had received from Dr Pitcairne. Pitcairne died in Edinburgh on the 20th of October 1713. He had been a great collector of books, and his library, which is said to have been of considerable value, was, through the influence of Ruddiman, disposed of to Peter the Great of Russia.

PITCH. (1) (O. Eng. pic, an adaptation of Lat. picus, picis, Gr. πίς, πίς, allied with Gr. πῖς, pine-tree, Lat. pinus) the name of various substances of dark colour and of extremely viscous and tenacious consistency when subjected to heat. Strictly the term is applied to the resinsubstance obtained as a solid residuum by the distillation of wood-tar (see Tar), or the non-resinous substance similarly produced from Coal-tar (q.v.). The name is also applied to the natural mineral substances, i.e. asphalt or bitumen (q.v.). (2) A noun of various meanings which are somewhat difficult to connect with the verb from which they apparently must be derived. "To pitch" means primarily to thrust in or fix a stake or other pointed object into the ground, hence to place in a fixed position, set in order, cast or throw, hence to incline or slope. The etymology is obscure, but it appears in Northern dialects as "pick," of which it may be a variant; there is some difficulty in connecting this form with "pick," variant of "pike" (q.v.).

PITCH, MUSICAL. The pitch of a musical sound is naturally defined by its absolute position in the scale and by its relative position with regard to other musical sounds. It is precisely defined by a vibration number recording the frequency of the pulsations of a tense string, a column of air, or other vibrator, in a second of time. In Great Britain such a number is the vibration number to and fro (swing both ways of a pendulum) is taken as the unit; elsewhere the vibration in one direction only (swing one way of the pendulum). The only official standard is the French, dating from 1859, preserved by a tuning-fork vibrating 870 to 9° (double vib. 435.33) at a temperature of 15°C. (50°Fahr.) in a second. The vibration number stated in the edict establishing the Diapason Normal is 870 (435), which for comparison will be here adhered to. The natural basis for a standard musical pitch is the voice, particularly the male voice, which has been of greater importance historically. There is no reason to suppose the human voice has varied, during the period that has elapsed since the invention of writing, more than by the accidental attributes. The only difference to be reckoned with may be in recent tendencies of solo vocalists to sing for effect, and so to
extend the compass of the voice upwards. Otherwise we may assume no disturbing alteration has taken place for more than 2000 years in its position and extent. Vibrations increase in rapidity as the note rises and decrease as it falls. Any note may be a pitch note; for orchestras custom has settled upon \( a^4 \) in the treble clef, for organs and pianos in Great Britain \( c^1 \), and for modern brass instruments \( f^3 \).

We are not without a clue to the pitch usual in the classic Greek and Alexandrian ages: the vocal octave to which the lyre was adapted was noted as from \( e \) to \( e' \). As in choruses baritone and low tenor singers always prevail, \( d-a' \), at French or at medium pitch, would really be the Greek singing octave; we may therefore regard it as a tone lower than that to which we are accustomed. But to sing the lower Greek modes in or near the vocal octave it was necessary to transpose (μεραβόθη) a fourth upwards, which is effected in modern notation by a flat placed upon the \( b \) of the line of staff; thus modal diagrams have in their major key of \( C \) to that of \( F \). This transposition has had, as we shall see, much to do with the history of our subject, ultimately influencing the ecclesiastical chant and lasting until the 17th century of our era. It does not appear from any evidence that the keyboards—when there were more than one—of the early organs were arranged for transposition, but it is certain that the Flemish harpsichords to 1650 were made with double keyboards to accommodate it (see Hipkins' History of the Pianoforte, 1897).

But a positive identity of pitch cannot be claimed for any period of time, and certainly not for the early organs; the foot-rule of the organ-builder which had to do with the lengths of the pipes, and which varied in every country and province, could easily cause a difference of a semitone. Scale and wind-pressure are also important factors. But with all these often opposed conditions, we find less variation than might be expected, the main and really important divergence being due to the necessity of transposition, which added a very high pitch to the primarily convenient low one.

The first attempt to define pitch would seem to have been Arnold Schlick (Musica ausgeteutscht und ausgezogen, Heidelberg, 1522), who gives a measure, a line of 4½ Rhenish inches, which, he says, multiplied sixteen times, should be the lowest \( F \) of a small organ. He gives no diameter or wind-pressure. Dr. A. J. Ellis used this indication to have an organ pipe made which with one-sixteenth diameter and a wind-pressure of 31 in., at one-fourth Schlick's length, gave \( f^3 \) 301-6, from which he derived a just major third of \( a^1 \), which would compare very well with an old Greek \( a \). Schlick goes on to say the organ is to be suited to the choir and properly tuned for singing, that the singer may not be forced to sing too high or too low and the organist have to play chromatics, which is not handy for every one. Further, he says pitch cannot be exactly defined, because voices vary; he nevertheless gives the measure above mentioned for the low \( F \), but if a larger organist inclines to our still lower \( C \), then this \( C \) must be of the same measurement, the reason being that a greater part of church music ends in "grambus," a word understood by Schlick's editor to mean the transposition of a fourth. The larger high-pitch organ will therefore be at \( a^1 \) 302-6. The Halberstadt organ, about which so much has been written, was, according to Praetorius (Syntagma musicum, Wöllfenbüttel, 1618), built in 1561, and repaired or rebuilt 1565. He gives the longest pipe of this organ, B natural, as 31 Brunswick feet, and the circumference 33 ft. He further tells us this pitch was a tone, nearly a tone and a half, higher than a suitable church pitch (Chorton), for which he gives a diagram. Dr. Ellis had pipes (now preserved in the Royal Institution, London) made to reproduce both these pitches at 3½ in. wind-pressure. The Halberstadt pitch was found to be \( a^4 \) 309-8; the Chorton, 424-2. Ellis used mean-tone temperament in calculating this lower pitch; but as he used just intonation for the Halberstadt, it seems preferable to substitute it for the Chorton, thus reducing it to \( a^4 \) 422-8. Praetorius's Cammer ton, or chamber pitch, formulated in his diagrams for voices and instruments, is, he says, a whole tone higher; equivalent, therefore, to \( a^4 \) 475-65. Nearly all the German organs in his time were tuned to this higher pitch. Ellis offered the suggestion of a much higher pitch for this Cammer ton in his lecture "On the History of Musical Pitch," read before the Society of Arts, London (Journ. Soc. Arts, March 5, 1888), but the present writer is unable to accept it. The lower vibration number is justified only by consideration of the voice divisions of the male voice, bass, tenor and alto, as given by Praetorius, whose Cammer ton very closely corresponds with Bernhardt Schmidt's Durham organ, 1663-1668, the original pitch of which has been proved by Professor Armes to have been \( a^4 \) 474-1. The Halberstadt pitch is nearly a semitone higher, which again agrees with the statement of Praetorius, and also Schlick's high \( C \) organ. Yet it would seem there had been a still higher pitch used in the old ecclesiastical music. Upon this interesting question Praetorius is confused and difficult to understand, but he never wavers about the transposition of a fourth. In one passage he distinctly says the old pitch in this high pitch had been a fourth higher than his Cammer ton, with which we shall find his tertia minore combines to make the required interval. The term tertia minore, or inferiore, is used by Praetorius to describe a low pitch, often preferred in England and the Netherlands, in Italy and in some parts of Germany. An organist, instead of transposing a whole tone down from the Cammer ton, would for the tertia minore have to transpose a minor third. A corroboration of this pitch is found in A. Silbermann's great organ in Strasbourg minster (1713-1716), the pitch of which, taken in 1886 and reduced to 59² Pahr. (as are all pitches in this article), is \( a^1 \) 393-2. An old contemporary says of it: "There were three diapasons, one almost as large as the organ. Sir Frederick Gore Ouseley (side Ellis's lecture) regarded the French ton de chapelle as being about a minor third below the Diapason Normal, \( a^4 \) 435, and said that most of the untouched organs in the French cathedrals were at this low pitch. Strasbourg was French territory in 1713, but Silbermann's organ is not quite a whole tone below. Ellis quotes an organ at Lille, \( a^4 \) 374-2, but no other instance of the very low Schlick pitch is recorded, although trial of the French cathedral organs might perhaps result in the finding of examples. Ellis gives Dom Bédos (L'Art du facteur d'orgues, Paris, 1766) as authority for a mean tone \( a^4 \) 376-6. To return to the tertia minor, Dr. R. Smith, of Cambridge, in 1759, had the organ of Trinity College, built by Bernhardt Schmidt, lowered a whole tone, to reduce it to certain Roman pitch pipes made about 1720. His determinations of pitch by a weighted wire are not trustworthy; Ellis thinks they are not safe within four or five vibrations per second, but gives a mean pitch for this organ, when altered, of \( a^4 \) 392-7. St Michael's church at Hamburg, built as late as 1762 and unaltered in 1886, had a 17th-century pitch, \( a^4 \) 407-9. This is about a semitone below the Diapason Normal, and a just minor third lower than the St Jacobi organ in the same city (1688), measured by Herr Schmahl, \( a^4 \) 450-2. What was said in this regard about the German pipes would apply here also; there is an equal minor third lower, \( a^4 \) 411-4. The difference of a minor third, or, as we shall see later, a whole tone, had replaced the earlier fourth. Sir Frederick Gore Ouseley's comparison of the church and chamber pitches of Orlando Gibbons (side Ellis's lecture) clearly shows the minor third in Great Britain in the first half of the 17th century. But the narrowing continued. Bernhardt Schmidt, better known in England as Father Smith, was invited about 1660 to build the organ for the Chapel Royal, Whitehall; two years later he built the organ in Durham Cathedral \( a^4 \) 424-1, difference a whole tone, and practically agreeing with the Cammer ton of Praetorius. The Hampton Court organ of 1760 shows that Schmidt had further lowered his pitch a semitone, to \( a^4 \) 441-7. What happened at Durham was that at some subsequent date the pipes were shifted up a semitone to bring the organ into conformity with this lower pitch, with which it is probable Schmidt's organ in St Paul's and the Temple, and also Trinity College, Cambridge, agreed. This lowering tendency towards the low church pitch, and the final adoption of the latter as a general mean pitch throughout the 18th century, was no doubt influenced by the introduction of the violin, which would not bear the high tension to which the
utes and viols had been strained. Harpsichords had long been preferred at the *tortia minore*. The *Chorton of Practorius*, $a^1 422-8$, is practically the same pitch as that of the fork of the possession of which has been attributed to Handel, $a^1 422-5$. It is a very fair mean between G. Silbermann's 18th-century Dresden pitch, $a^1 415$, and the organs of Renatus Harris, $a^1 428-7$. Stein tuned Mozart's piano to a fork $a^1 421-6$, and the Broadwood pianos used at the London Philharmonic Society in its first concerts ($1813$) were tuned to a fork $c^2 506-8$, which gives a mean tone $a^1 423-7$.

According to Schindler (*Niederrheinische Musik-Zeitung, 1855, Nos. 8 and 9*) and the report of the French Commission, 1823, the rise in pitch began at the Congress of Vienna in 1816, the military bands being the cause. With the improvements in wind instruments this continued, as a more brilliant effect was gained. In 1823 Weber’s *Euryanche* is recorded as having been played in Vienna at $a^1 437-5$, and in 1834 Kreutzer’s *Nachlager* at $a^1 440$. The measurements are doubtful, but the upward tendency is clear. Scheiber, by his simple and accurate tonometer, has recorded pitches in Vienna about 1834 from $a^1 433-9$ to $440-2$. About that time, or it may be a few years earlier, Sir George Smart established a fork for the Philharmonic Society, $a^1 433-2$. Forks intended for this vibration number, such as the Paris fork, were sold as early as 1840. But about that year the performing pitch of the Society had reached $452-5$. Sir Michael Costa was the conductor 1846–1854, and from his acceptance of that high pitch the fork became known as Costa’s, and its inception was attributed to him, though on insufficient grounds. In 1874 a further rise in the fork to $a^1 454$ was instigated by Sir Charles Hallé. The British army is bound by His Majesty’s Rules and Regulations to play at the Philharmonic pitch, and a fork tuned to $a^1 452-5$ in 1890 is preserved as the standard for the Military Training School at Kneller Hall. But the Philharmonic Society adopted the Diapason Normal in 1865, and the military bands have not gone with it. In point of fact the pitch has only gone higher, and the brass bands, which are so important in the North of England and in Wales, are not behind them.

It was the irrefutable upward tendency that caused the French government in 1859, acting with the advice of Halévy, Meyerbeer, Auber, Ambroise Thomas and Rossini, to establish by law the *Diapason Normal*. Other countries have gradually followed, and, with few exceptions, the low pitch derived from the Diapason Normal may be said to prevail throughout the musical world. Great Britain has been the last to fall in, but the predominance of the low pitch, introduced at Covent Garden Opera in 1818, is assured. The proprietors of Queen’s Hall, London, did much to encourage the fork, but they took the alteration, at great expense, of their large concert organ, which had only just been erected. In 1866 the Philharmonic Society decided upon a performing pitch, ostensibly at 68° Fahr., of $a^1 439$; and in 1899 Messrs Broadwood made a successful effort to get this vibration number accepted by their competitors in Great Britain. The high pitch remains only where there are large concert organs not yet lowered, and with the military and brass bands.

The consideration of temperature as affecting the use of a standard pitch was not attended to when the French government issued its ordinance. The 15° Centigrade attached to the description of the standard fork in Paris was intended for the definition and verification of the fork only. The alteration of the fork due to heat is scarcely perceptible, but wind instruments, and particularly the organ, rise almost proportionately to the increase in temperature of the surrounding air, because sound travels at an enhanced rate as the temperature rises. The coefficient of this rise is equivalent to half a vibration ($0.5$) per degree Fahr., per second. D. J. Blaikley (*Essay on Musical Pitch, Catalogue of the Royal Military Exhibition, Chelsea, 1890*), and Victor Mahillon (*Catalogue descriptif et analytique du Musée, Bruxelles, troisième volume, appendice, 1900*) have recorded these experiences of wind instruments under changes of temperature. The French Commission, in establishing the Diapason Normal, should have chosen a temperature of 20°C.

There would then have been less disturbance owing to the breath of the players and heat of the theatres or concert-rooms. It would be a great advantage to get this higher grade generally adopted. It was proposed in the Stimm-Conferenz at Vienna in 1885, but not carried. Table III. showing orchestral pitches obtained in 1899, for the measurements of which the writer is responsible, prove how chimerical it is to hope for greater accuracy than is found between 435 and 440 vibrations a second for $a^1$, inasmuch as temperature must always be reckoned with.

Verified by A. J. Hipskins. But for Leipzig a comparison with the Gewandhaus Band may be sought.

(A. J. H.)

PITCHBLENDE, or URANINITE, a mineral species consisting essentially of uranium oxide, of importance as a source of uranium and radium. It is a very heavy (specific gravity 9-0 - 9-7), compact mineral with a conchoideal to uneven fracture, and a brownish to velvet-black colour and pitchy lustre. Crystals are rare; they have the form of regular octahedra or less often of cubes. The hardness is 5½, and the streak is brown with a greenish tinge. The mineral has been known to occur at Joachimsthal in Bohemia since 1777, and it was early called pitchblende, because of its appearance; but its true nature was not recognized until 1789, when M. H. Klapper's analysis of it resulted in the discovery of the element uranium. Analyses of material from different localities exhibit wide variations in chemical composition. In addition to uranium oxides, there are thorium, cerium (and lanthanum), yttrium and lead oxides, each varying in amount from a trace up to 10%. Calcium, iron, magnesium, manganese, silica, water, &c., are also present in small amounts. The amounts of uranium and uranin oxides (UO₃, 21-72; UO₂, 13-59%) also vary considerably. The mineral is often described as a uranite of uranyl lead, thorium and cerium; but in the least altered material from Branchville in Connecticut the uranous oxide predominates, whilst in altered specimens uraninite is in excess. In the closely allied mineral, thorianite, thorium predominates (ThO₂; 76; UO₂, 13%). Since the dioxide of uranium, thorium and cerium may be obtained artificially as cubic crystals, it seems probable that pitchblende consists of isomorphous mixtures of these dioxides, the uranium oxide being due to oxidation.

The radio-active properties of pitchblende are of special interest. The fact that this mineral is more strongly radio-active than metallic uranium led to the discovery in it of the elements radium, polonium and actinium. When pitchblende is ignited or dissolved in dilute sulphuric acid, a gas is evolved which consists largely of helium and argon: terrestrial helium was first recognized in this mineral.

The mineral occurs either as a primary constituent of granite rocks or as one of secondary origin in metallic veins. Octahedral crystals ("elevite" and "bröggerite") occur in the pegmatitic veins of southern Norway, being occasionally found in the felspar quartaries at Moss, Arendal and other places. Crystals are found under similar conditions at Middletown and Branchville in Connecticut, Lima county in Texas ("rivenite"), Mitchell county in North Carolina, Villequive in Quebec, and other American localities. Thorianite, found as water-worn cubes in the gem-graves near Balangoda in Sabarangamuwa province, Ceylon, has also no doubt been derived from crystalline rocks. On the other hand, the mineral found in metallic veins, and to which the name pitchblende is more properly restricted, never occurs as crystals, but as compact masses rendered more or less impure by admixture of other minerals, the specific gravity being sometimes as low as 6-5; thorium, cerium, &c., are absent, and radium and helium are present in smaller amounts. This variety occurs with ores of silver, lead, copper, nickel, cobalt, bismuth, &c., at Jäkhoogenenstadt, Marienberg and Schneeberg in Saxony, Joachimsthal and Prizbam in Bohemia, Režňany in Bihar Mountains in Hungary, Gilpin county in Colorado, St. Just, in Penwith, Redruth, Grampound Road and elsewhere in Cornwall.

Often associated with pitchblende, and resulting from its alteration, is an orange-yellow, amorphous, gum-like mineral called gummit, which is a hydrous uranium oxide with small amounts of lead, calcium, iron, &c.

(P. L. S.)

PITCHER. (1) A large vessel for holding liquids, derived through Fr. from Med. Lat. *pictum*; the Lat. variant *bicium*, Gr. *βίκειος*, has given the Ger *Becher*, Eng. beaker (g.v.). (2) One who "pitches," i.e. throws, casts, fixes; the name of the player in the game of base-ball who pitches or delivers the ball to the striker.

PITCHER PLANTS. In botany, the name given to plants in which the leaves bear pitcher-like structures or are pitcher-like in form. The plant generally understood by this name is *Nepenthes*, a genus containing nearly sixty species, natives of tropical Asia, north Australia (and one only) of Madagascar. North Borneo is especially rich in species. They are shrubby plants climbing over surrounding vegetation by means of tendril-like prolongations of the midrib of the leaf beyond the leaf-tip.

![Fig. 1.—Pitcher of Nepenthes distillatoria.](image_url)

A. Honey-gland from attractive C, Transverse section of the same.
B. Digestive gland from interior of pitcher, in pocket-like depression of epidermis, opening downwards.

The pitcher is a development at the end of the tendril. It is generally tubular in form, but in some species two forms are produced on the same plant, lower or terrestrial goblet-shaped pitchers and upper suspended pitchers retaining the more primitive more or less tubular form; in a few species a third form—funnel- or cornucopia-shaped pitchers—occurs in the upper part. In the terrestrial type a pair of well-developed wings traverse the length of the pitcher; in the tubular or funnel-shaped form the wings are narrow or ridge-like. The mouth of the pitcher has a corrugated rim (peristome) formed by incising of the margin, the convex surface of which is firm and shining. It is traversed by more or less prominent parallel...
ridges, which are usually prolonged as teeth beyond the infolded margin. Above the mouth is the lid (operculum), which varies in size from a small narrow process to a large heart-shaped expansion. A study of the development of the pitcher, especially in the young pitchers of seedling plants, shows that the inflated portion is a development of the midrib of the leaf, while the wings, which are especially well represented in the terrestrial type of pitcher, represent the upper portion of the leaf-blade which has become separated from the lower portion by the tendril; the lid is regarded as representing two leaflets which have become fused. The short straight or curved process from the back of the pitcher behind the lid represents the organic apex of the leaf (A in fig. 1).

The size of the pitcher varies widely in the different species, from an inch to a foot or more in depth. The colour also varies considerably, even in different pitchers of the same individual, according to age, light exposure or soil conditions. It is uniformly green or more or less spotted, blotted or suffused with red or crimson, or sometimes, as in N. sanguinea or N. Edwardsiana, largely or wholly of a rich scarlet or crimson colour. Insects are attracted to the mouth of the pitcher by a series of glands, yielding a sweet excretion, which occurs on the stem and also on the leaf from the base of the leaf-stalk to the lid and peristome. Embedded in the incurved margin of the rim which affords a very insecure foothold to insects, are a number of large glands excreting a sweet juice. The cavity of the pitcher is in some species lined throughout with a smooth glistening surface over which glands are uniformly distributed; these glands secrete a liquid which is found in the pitcher even in the young state while it is still hermatically closed by the lid. In other species the glands are confined to the lower portion of the cavity surface, while the upper part bear a smooth waxy secretion on which it is impossible, or at any rate extremely difficult, for insects to secure a foothold. This area is termed the "conducting" area, as distinguished from the lower or "detentive" gland-bearing area. It has been proved that the secretion contains a digestive ferment capable of rendering proteid matter soluble. Insects, especially running insects, which have followed the track of honey glands upwards from the stem along the leaf, reach the mouth of the pitcher, and in their efforts to sip the attractive marginal glands fall over into the liquid. The smooth walls above the liquid afford no hold, and they are drowned; their bodies are digested and the products of digestion are ultimately absorbed by the glands in the pitcher-wall. Thus Nepenthes secures a supply of nitrogenous food from the animal world in a manner somewhat similar to that adopted by the British sundew, butterwort, and other insectivorous plants.

The side-saddle plant, Sarracenia, native of the eastern United States, is also known as a pitcher-plant. There are about seven species, herbs with clusters of radical leaves some or all of which are more or less trumpet- or pitcher-shaped. The leaf has a broadly sheathing base succeeded by a short stalk bearing the pitcher, which represents a much enlarged midrib with a wing-like lamina. Above the rim of the pitcher is a broad flattened lid, which is also a laminar development. The surface of the leaf, especially the laminar wing, bears glands which in spring exude a large glistening drop of nectar. The lid and mouth of the pitcher are brighter coloured than the rest of the leaf, which varies from yellow-green to deep crimson in different species and in individuals according to exposure to sunlight and other conditions. This forms the attractive area, and the inner surface of the lid also bears numerous glands, as well as downward-pointing hairs, each with a delicately striated surface (fig. 2, A). Below it is the conducting surface (B) of glassy epidermal cells, with short downward-directed points, which facilitate the descent, but impede the ascent of an insect. Then come the glandular surface (C), which is formed of smooth polished epidermis with numerous glands that secrete the fluid contents of the pitcher, and finally the detentive surface (D), of which the cells are produced into long and strong bristles which point downwards and meet in the centre of the diminishing cavity so as to render escape impossible. The secretion wets an insect very rapidly, but, so far as is known, seems to be completely destitute of digestive power—indeed, rather to accelerate decomposition. The pitchers accumulate vast quantities of insects in the course of a season, and must thus abundantly manure the surrounding soil when they die. Moreover, the

a, Apex of leaf.
feast is largely shared by unbidden guests. Not to speak of insects which feed upon the pitcher itself, some drop their eggs into the putrescent mass, where their larvae find abundant nourishment, while birds often alit open the pitchers with their beaks and devour the maggots in their turn.

Cephalotus foliiculosis, a native of south-west Australia, a small herbaceous plant, bears ordinary leaves close to the ground as well as pitchers. The latter somewhat resemble in general form those of Nepenthes. The lid is especially attractive to insects by its bright colour and honey secretion; these wings lead up to the mouth of the pitcher, on the inside of which a row of sharp spines points downwards, and below this a circular ridge (r, fig. 3) armed with papillae serves as a conducting area. A number of glands on the interior of the pitcher secrete a plentiful fluid which has digestive properties.

Comparison with monstrous forms shows that the pitcher of Cephalotus arises by a calceolate pouching from the upper surface of the ordinary spathe leaves, the lid here arising from the proximal side of the pitcher-orifice.

PITCHSTONE (German Pechstein, from its resemblance to pitch), in petrology, a glassy igneous rock containing a residuum which in appearance resembles pitch, or a mass vassilised by some basaltic type. It differs from obsidian principally in its rather dull lustre, for obsidian is bright and vitreous in appearance; all pitchstones also contain a considerable quantity of water in combination amounting to from 5 to 10% of their weight or 10 to 20% of their volume. The majority of the rocks of this class occur as intrusive dikes or veins; they are glassy forms of quartz porphyry and other dike rocks. Their dull lustre may be connected with the great abundance of minute crystalites and microites they nearly always contain. These are visible only in microscopic sections, and their varied shapes make pitchstones very interesting to the microscopic observer. Another pitchstone is a Devonian (e.g. the glassy nect of the Tag Bridge in Fife, Scotland, and the andesite-pitchstones of the Cheviot Hills), most of them are Tertiary or recent, as like all natural glasses they tend to crystallize or become devitrified in course of time. In some of the older pitchstones the greater part of the mass is changed to a dull felsitic substance, while only nodules or kernels of unaltered glass remain.

Some pitchstones are very acid rocks, containing 70 to 75% of silica, and have close chemical affinities to garnites and rhyolites. Contaminated with quartz, glasses can be obtained with an increasingly vitreous types of trachyte or keratophyre; others have the composition of diachte and andesite, but the black basaltic glasses are not usually classified among the pitchstones. Very fine-grained pitchstones occur at Chemnitz and Meissen in Saxony. They are brown or dark green, very often perlitic (see Petrology, Plate I., fig. 5), and show progressive devitrification starting from cracks and joints and spreading inwards through the mass. For a long time the pitchstone dikes of Arran in Scotland have been famous among geologists for the great beauty and variety of crystalite crystals they contain. These pitchstones are dull green in hand specimens. Some of them contain phenocrysts or augite, others are not, but in all there is an abundance of branching feathery crystalline growths in the ground mass: they resemble the branches of fir trees or the fronds or ferns, minute crystallite rods being built together in aggregates which spread out like the thin paper of a window-pane. It is supposed that the mineral they consist of is hornblende. In addition to these larger growths there are many small microites scattered through the glass, also hair-like trichites, and fine rounded globules.

When phenocrysts are present the small crystals are planeed on the surfaces like grass growing from a turf-covered wall. These pitchstones are believed to proceed from the great eruptive centres which were active in western Scotland in early Tertiary times. Another pitchstone is a basaltic variety which forms a great scraggy ridge or scuring in the island of Egg (Scotland). At one time regarded as a lava flow occupying an old stream channel it has recently been described as an intrusive sheet. It is from 200 to 300 ft. thick. The rock is a dark green, blackish pitchstone-porphyry, with glowing idiomorphic crystals of felspar in a vitreous base. It contains no quartz; the felspars are anorthoclase, and with them there are numerous crystals of green augite. The ground mass contains small crystals of felspar, and is of a rich brown colour in thin section with well-developed pleochroitic structure (see Petrology, Plate II., fig. 1).

The chemical composition this rock resembles the trachytes rather than the rhyolites. It is an egg and Skye there are many dikes of pitchstone, mostly of intermediate rather than of acid character, all connected with the great eruptive activity which characterized that region in early Tertiary times.

The following analyses give the chemical composition of a few well-known pitchstones:

PITSCSI (Pitisci), also written PITESTI and PITEST, the capital of the department of Argesh, Rumania; situated among the outlying hills of the Carpathians, on the river Argesh, which is here joined by several smaller streams. Pop. (1900), 15,570. The surrounding uplands produce good wine, fruit and grain, besides being rich in petroleum and salt; and, as the main Walachian railway is met at Pitisci by lines from Câmpulung and Hermannstadt in Transylvania, the town has a considerable trade. It has manufacures of lacquer and varnish.

PITH (O.E. pitha, cognate with Du. pith, kernel of a nut), properly the medulla, the central column of spongy cellular tissue, in the stems of dicotyledonous plants (see Plants: Anatomy). The word is thence applied to the spinal cord or marrow in animals, to the medullary end of a hair, and to that which forms the central part or core of any object or substance; hence, figuratively, vigour, energy, concentrated force. Very light hats or helmets are made of the dried pith of the Indian spongwood or hat plant (Asechnome aspera, the native name being Soloh). These pith hats are worn by Europeans in India and the East. The plant (Pistacia papryracea), from the pith of which the delicate white film known as "rice-paper" is made, is also known as the pith-plant.

PITfANrHtmPUS tERctus (Erect Ape-Man), the name given by Dr Eugene Dubois, of the Dutch army medical service, to the imaginary creature which he constructed from fossilized remains found by him in Java. These fragments consisted of a thigh-bone, two teeth, and the upper part of a skull, and were unearthed in 1891-1892 on the left bank of the Bengawan River near Trinil. The skull appears to have been low and depressed with strong supracleural ridges; the teeth are very large, and the femur is quite human. The teeth and jaws were found together, the femur a few yards away a year afterwards. The discoverer, however, stated it as his belief that the fragments were portions of the same skeleton and belonged to a creature half-way between man and the higher apes and of the Pleistocene age. Much discussion followed the "find," and many authorities have given an opinion adverse to Dr Dubois's theory. The prevailing opinion is that the bones are human. They are not held to represent what has been called "the missing link," bridging over the gulf between man and the apes; but almost all authorities are agreed that they constitute a further link in the chain, bringing man nearer his Simian prototype. L. Manouvrier concludes that Homo javanicus walked erect, was of about medium height, and was a true precursor, possibly a direct ancestor, of man. He calls attention to the fact that the cranial capacity decreases in proportion to the antiquity of the human skulls found, and that the pithecanthropus skull has a capacity of from 900 to 1000 cc.—that is, "stands at the level of the smallest which have been occasionally found amongst the reputedly lowest savage peoples."

See Dubois, Pithecanthropus erectus (Batavia, 1894); a later paper read by Dr Dubois before the Berlin Anthropological Society was translated in the Smithsonian Report for 1898. Also a paper read by Dr D. J. Cunningham before the Royal Dublin Society, January 23, 1895 (reported in Nature, February 28, 1895); O. C. Marsh,
PITHIVIERS, a town of north central France, capital of an arrondissement in the department of Loiret, 28 m. N.E. of Orleans, on the railway to Malesherbes. Pop. (1896), 5676. The church of St Solomon, chiefly in the Renaissance style, and remains of the ancient ramparts are of interest. Statues have been erected of the mathematician Denis Poisson (d. 1840), and of the physician and agriculturist Duhamel de Monceau (d. 1782), natives of Pithiviers. The town is an agricultural market, and an important centre for the saffron of the region of Gâtinaires the cultivation of which, originally introduced by the Jews of Avignon in the 13th century was fostered by Louis XIV. The shrine of St Solomon in the 9th century and that of St Gregory, an Armenian bishop, in the 10th, formed the nuclei of the town; and the donjon built at the end of the 10th century for Hélöise, lady of Pithiviers, was one of the finest of the period.

PITHOM, one of the "treasure cities" stated to have been built for Pharaoh by the Hebrews in Goshen during the Oppression (Exod. i. 11). We have here the Hebraized form of the Egyptian Petén "House of the (sun-god) Etôm," in Greek, Patúmos, capital of the 9th nome of Lower Egypt and situated in the Wadi Tumilat on the canal by which the Nile to the Red Sea, Succoth (Egyptian Tukhet) was identical with it or was in its immediate neighbourhood. The site, now Tell el Maskhuta, has yielded several important monuments, including the best preserved of the trilingual stela of Darius which commemorated his work on the canal. The earliest name yet found is that of Ramessu II. of the XIXth Dynasty, but in one case it has usurped earlier work, apparently of the XIXth Dynasty (a sphinx), and the city was evidently very ancient. Several of the monuments from Pithom have been removed to Ismailia on the Suez Canal.

See Ed. Naville, "The Store City of Pithom and the route of the Exodus" (London, 1885); W. M. F. Petrie, Tanis, pt. i. (London, 1885); W. Goldschleff, "Stèle de Darius" in Recueil de travaux relatifs à la phalèscope et à l'archéologie égyptiennes et assyriennes, xii. 99, and the article RAMÉSES, (F. L. G.)

PITHOU, PIERRE (1539-1596), French lawyer and scholar, was born at Paris on 31st November 1539. His taste for literature was early seen, and his father Pierre (1494-1566) cultivated it to the utmost. He was called to the Paris bar in 1560. On the outbreak of the second war of religion in 1567, Pithou, who was a Calvinist, withdrew to Sedan and afterwards to Basel, whence he returned to France on the publication of the edict of pacification. Soon afterwards he accompanied the duc de Montmorency on his embassy to England, returning shortly before the massacre of St Bartholomew, in which he narrowly escaped with his life. Next year he followed the example of Henry of Navarre by abjuring the Protestant faith. Henry, shortly after his own accession to the throne of France, recognized Pithou's talents and services by bestowing upon him various legal appointments. The most important work of his life was his co-operation in the production of the Satire Monâpide (1593), which did so much to damage the cause of the League; the harangue of the Sieur d'Aubray is usually attributed to his pen. He died at Nogent-sur-Seine on the 1st of November 1596. His valuable library, specially rich in MSS., was for the most part transferred to what is now the Bibliothèque Nationale in Paris.

Pithou wrote a great number of legal and historical books, besides preparing editions of several ancient authors. His earliest publication was the Digestum subsectorum lib. i. (1565). Perhaps his most distinguished edition of the Leges Vistigorum (1579) was his most valuable contribution to historical science; in the same line he edited the Codicula of Charlemagne, Louis the Pious, and Charles the Bald in 1586, and he also assisted his brother François in preparing an edition of the Corpus juris canonici (1687). His Liberis de l'église gallicane (1594) is reprinted in his Opera sacra juridica et oris miscellanea collecta (1606). In classical literature he was the first who made the world acquainted with the Tables of Plutarch (1596); he also edited the Persuasion Veneris (1587), and Juvenal and Persius (1585).

Three of Pithou's brothers acquired distinction as jurists: JEAN (1524-1602), author of the works of that name, in collaboration with his twin brother NICOLAS (1524-1598), of Institution du mariage chrétien; and FRANCOIS (1534-1621), author of Glossarium ad libros capitationum (1588), Traité de l'excommunication et de l'absolution (1618).

PITIGLIANO, a town in Italy, province of Grosseto. Pop. (1901), 4416. It is the cathedral city of the bishopric named after the neighbouring town of Sovana, and possesses a 16th-century cathedral and a church of the 11th-15th centuries, Pitiogiano was originally a fief of the countship of Sovana, which in 1203 came by marriage into the possession of the Orsi. In 1410 Sovana was taken by the Siennese, but by the terms of a peace concluded in 1417 the Orsini retained Pitigliano, Gentile Orsini (assassinated 1434) assuming the title of count of Pitigliano. The most famous of the line of counts was Niccolo III. (1442-1510), a celebrated condottiere. Under his successors Pitigliano became the scene of ceaseless family feuds culminating in assassination. In 1562 the Madonna of Firenze seized part of their territories, and acquired the rest by exchange in 1580. The Orsini stronghold still stands in the town.

PITLOCHRY, a village of Perthshire, Scotland, 28 m. N.W. of Perth by the Highland railway. Pop. (1901), 1541. It lies on the left bank of the Tummel, a little below the confluence of that river and the Garry, 350 ft. above the sea. It is a favourite health resort and tourist centre. Among the immediate attractions are the pass of Killiecrankie, the falls of Tummel, the exquisite prospect called "Queen's View" (named after Queen Victoria) and Loch Tummel, 8 m. to the west. One m. S.E. of the village is the Black Spout, a waterfall of 60 ft. formed by the Bruar.

PITMAN, SIR ISAAC (1813-1897), English phonographer, was born at Trowbridge, Wiltshire, on the 4th of January 1813, and was educated at the local grammar school. He started in life as a clerk in a cloth factory, but in 1831 he was sent to the Normal College of the British and Foreign School Society in London. Between 1832 and 1839 he held masterships at Barton-on-Humber and Wotton-under-Edge, but he was dismissed by the authorities when he became a Swedishman, and from 1839 to 1843 he conducted a private school of his own at Bath. In 1849 he took up Samuel Taylor's system of shorthand, and from that time he became an enthusiast in developing the art of phonography. He published a Phonographic System in 1842, and offered it to Samuel Bagster (1771-1852). The publisher did not accept the work, but suggested that Pitman should invent a new system (see SHORTHAND) of his own. The result was his Stenographic Soundhand (1837). Bagster's friendship and active help had been secured by Pitman's undertaking to verify the half-million references in the Comprehensive Bible, and he published the inventor's books at a cheap rate, thus helping to bring the system within the reach of all. Pitman devoted himself to perfecting phonography and propagating its use, and established at Bath a Phonetic Institute and a Phonetic Journal for this purpose; he printed in shorthand a number of 543 works, and his book with the title Phonography (1846) went through many editions. He was an enthusiastic spelling reformer, and adopted a phonetic system which he tried to bring into general use. Pitman was twice married, his first wife dying in 1857, and his second, whom he married in 1861, surviving him. In 1894 he was knighted, and on the 22nd of January 1897 he died at Bath. Sir Isaac Pitman popularized shorthand at a time when the advance of the newspaper press and modern business methods were making it a matter of great commercial importance. His system adapted itself readily to the needs of journalism, and he was able to use revolutionized the work of reporting. He was a non-smoker and a vegetarian, and advocated temperance principles.

His Life was written by Alfred Baker (1906) and (1902) by his brother, Benn Pitman (1822-1911).
PITONI, GIUSEPPE OTTAVIO (1657-1743), Italian musical composer, was born at Rieti on the 18th of March 1657. He came to Rome as a boy and sang in the choir of SS Apostoli. Foggia gave him instructions in counterpoint, and he became maestro di Cappella, first at Terra di Rotondo and later (1673) at Assisi. In 1676 he went to Rieti, and in 1677 to Rome, where he held various appointments, dying on the 1st of February 1743 as maestro di Cappella at St Marco, where he was buried. "Pitoni appears to have devoted himself exclusively to church music, and although he did not disdain the modern style with instrumental accompaniment, he is best known by his Masses and other works in the manner of Palestrina.

Several volumes of his autograph composition are in the Santini Library at Munich.

PITT, THOMAS (1653-1726), British East India merchant and politician, usually called "Diamond Pitt," was born at Blandford, Dorset, on the 5th of July 1653. In early life he went to India, and from his headquarters at Balasore he made trading journeys into Persia and soon became prominent among those who were carrying on business in opposition to the East India Company. Twice he was arrested by order of the company, the second time being when he reached London in 1683, but after litigation he obtained permission for some years in England he retired to India and to his former career. Unable to persuade him the East India Company took him into its service in 1695, and in 1697 he became president of Fort St George, or Madras. Pitt was now very zealous in defending the interests of his employers against the new East India Company, and in protecting their settlements from the attacks of the natives; in directing the commercial undertakings of the company he appears to have been very successful. Soon, however, he had a serious quarrel with William Fraser, a member of his council, and consequently he was relieved of his office in 1700, although he was afterwards consulted by the company on matters of importance. During his residence in India Pitt bought for about £50,000 the fine diamond which was named after him; in 1717 he sold this to the regent of France, Philip duke of Orleans, for £80,000 or, according to another account, for £135,000.

It is now the property of the French government. During his former stay in England Pitt had bought a good deal of property, including the manor of Old Sarum, and for a short time he had represented this borough in parliament. After his final return from India in 1710 he added to his properties and again became member of parliament for Old Sarum. He died at Swallowfield near Reading on the 28th of April 1726. His eldest son, Robert, was the father of William Pitt, earl of Chatham (q.v.); and of Thomas Pitt (d. 1719), whose son became the first Earl of Chatham; and Thomas Pitt (c. 1668-1720), having married Frances (d. 1772), daughter of Robert Ridgeway, 4th Earl of Londonderry (d. 1714), was himself created earl of Londonderry in 1726.

PITT, WILLIAM (1720-1806), English statesman, the second son of William Pitt, earl of Chatham, and of Lady Hester Grenville, daughter of Hester, Countess Temple, was born at Hayes, near Bromley, Kent, on the 28th of May 1726. The child inherited a name which, at the time of his birth, was the most illustrious in the civilized world, and was pronounced by every Englishman with pride, and by every enemy of England with mingled admiration and terror. During the first year of his life every month had its illuminations and bonfires, and every wind brought some messenger charged with joyful tidings and hostile standards. In Westphalia the English infantry won a great battle which arrested the armies of Louis XV. in the midst of a career of conquest; Boscauen defeated one French fleet on the coast of Portugal; Hawke put to flight another in the Bay of Biscay; Johnson took Niagara; Amherst took Ticonderoga; Wolfe died by the most envious of deaths under the walls of Quebec; Clive destroyed a Dutch armament in the Hugli, and established the English supremacy in Bengal; Coote routed Lally at Wadenshaw, and established the English supremacy in the Carnatic.

The nation, while loudly applauding the successful warriors, considered them all, on and on land, in Europe, in America, and in Asia, merely as instruments which received their direction from one superior mind. It was the great William Pitt who had vanquished the French marshals in Germany and French admirals on the Atlantic—who had conquered for his country one great empire on the frozen shores of Ontario and another under the tropical sun near the mouths of the Ganges. It was not in the nature of things that popularity such as he at this time enjoyed should be permanent. That popularity had lost its gloss before his children were old enough to understand that the earl of Chatham was a great man. The energy and vitality which had formerly fitted him for the direction of war were not needed in time of peace. The lofty and spirit-stirring eloquence which had made him supreme in the House of Commons often fell dead on the House of Lords. Chatham was only the ruin of Pitt, but an awful and majestic ruin, not to be contemplated by any man of sense and feeling without emotions resembling those which are excited by the remains of the Parthenon and of the Colosseum. In one respect the old statesman was eminently happy. Whatever might be the vicissitudes of his public life, he never failed to find peace and love by his own heart. He loved all his children, and was loved by them; and of all his children the eldest, though he was the most ambitious of them all, was the most devoted to him.

The child's genius and ambition displayed themselves with a rare and almost unnatural precocity. At seven the interest which he took in grave subjects, the ardour with which he pursued his studies, and the sense and vivacity of his remarks on books and on events amazed his parents and instructors. One of his sayings of this date was reported to his mother by his tutor. In August 1766, when the world was agitated by the news that Mr Pitt had become earl of Chatham, little William exclaimed, "I am glad that I am not the oldest son. I want to speak in the House of Commons like papa." At fourteen the lad was in intellect a man. Hayley, who met him at Lyme in the summer of 1773, was astonished, delighted, and somewhat overawed, by hearing wit and wisdom from so young a mouth. The boy himself had already written a tragedy, bad, of course, but not worse than the tragedies of his friend. This piece (still preserved) is in some respects highly curious. There is no love. The whole plot is political; and it is remarkable that the interest, such as it is, turns on a contest about a regency. On one side is a faithful servant of the Crown, on the other an ambitious and unprincipled conspirator. At length the king, who had been missing, reappears, resumes his power and rewards the faithful defender of his right. A reader who should judge only by internal evidence would have no hesitation in pronouncing that the play was written by some Pittite poetaster at the time of the rejoicings for the recovery of George III. in 1789.

The pleasure with which William's parents observed the rapid development of his intellectual powers was alloyed by apprehensions about his health. He shot up alarmingly fast; he was often ill, and always weak; and it was feared that it would be impossible to rear a stripling so tall, so slender, and so feeble. Port wine was prescribed by his medical advisers; and it is said that he was, at fourteen, accustomed to take this agreeable physic in quantities which would, in our more abstemious age, be thought much more than sufficient for any full-grown man. It was probably on account of the delicacy of his frame that he was not educated like other boys of the same rank. Almost all the eminent English statesmen and orators to whom he was afterwards opposed or allied—North, Fox, Shelburne, Windham, Grey, Wellesley, Grenville, Sheridan, Canning—went through the training of great public schools. Lord Chatham had himself been a distinguished Etonian; and it is seldom that a distinguished Etonian forgets his obligations to Eton. But William's infirmities required a vigilance and tenderness such as could be found nowhere else. He was therefore bred under the paternal roof. His studies were superintended by a clergyman named Wilson; and those...
studies, though often interrupted by illness, were prosecuted with extraordinary success. He was sent, towards the close of the year 1773, to Pembroke Hall, in the university of Cambridge. The governor to whom the direction of William's academical life was confided was a bachelor of arts named Pretyman, who had been senior wrangler in the preceding year, and, who though not a man of prepossessing appearance or brilliant parts, was eminently acute and laborious, a sound scholar, and an excellent geometrician. A close and lasting friendship sprang up between the pair. The disciple was able, before he completed his twenty-eighth year, to make his preceptor bishop of Lincoln and dean of St Paul's; and the preceptor showed his gratitude by writing a life of the disciple, which enjoys the distinction of being the worst biographical work of its size in the world. Pitt, till he graduated, had scarcely one acquaintance, attended chapel regularly morning and evening, dined every day in hall, and never went to a single evening party. At seventeen he was admitted, after the fashion of those times, by right of birth, without any examination, to the degree of master of arts. But he continued during some years to reside at college, and to apply himself vigorously, under Pretyman's direction, to the study of the place, while mixing freely in the best academic society.

The stock of learning which Pitt laid in during this part of his life was certainly very extraordinary. The work in which he took the greatest delight was Newton's *Principia*. His liking for mathematics, indeed, amounted to a passion, which, in the opinion of his instructors, themselves distinguished mathematicians, required to be checked rather than encouraged. Nor was the youth's proficiency in classical learning less remarkable. In one respect, indeed, he appeared to disadvantage when compared with even second-rate and third-rate men from public schools. He had never, while under Wilson's care, been in the habit of composing in the ancient languages; and he therefore never acquired the knack of versification. It would have been utterly out of his power to produce such charming elegiac lines as those in which Wellesley bade farewell to Eton, or such Virgilian hexameters as those in which Canning described the pilgrimage to Mecca. But it may be doubted whether any scholar has ever, at twenty, had a more solid and profound knowledge of the two great tongues of the old civilized world. He had set his heart on being intimately acquainted with all the extant poetry of Greece, and was not satisfied till he had mastered Lycurgus's *Cassander*, about which he paid comparatively little attention. He knew no living language except French; and French he knew very imperfectly. With a few of the best English writers he was intimate, particularly with Shakespeare and Milton. The debate in Pandemonium was, as it well deserved to be, one of his favourite passages; and his early friends used to talk, long after his death, of the just emphasis and the melodious cadence with which they had heard him recite the incomparable speech of Belial. He had indeed been carefully trained from infancy in the art of managing his voice, a voice naturally clear and deep-toned. At a later period the wits of Brooke's, irritated by observing, night after night, how powerfully Pitt's sonorous echo rang in their ears, recommended him to him. He was approached him with having been "taught by his dad on a stool".

His education, indeed, was well adapted to form a great parliamentary speaker. The classical studies of Pitt had the effect of enriching his English vocabulary, and of making him wonderfully expert in the art of constructing correct English sentences. His practice was to look over a page or two of a Greek or Latin author, to make himself master of the meaning, and then to read the passage straight forward into his own language. This practice, begun under his first teacher Wilson, was continued under Pretyman. Of all the remains of antiquity, the orations were those on which he bestowed the most minute examination. His favourite employment was to compare harangues on opposite sides of the same question, to analyse them, and to observe which of the arguments of the first speaker were refuted by the second, which were evaded, and which were left untouched. Nor was it only in books that he at this time studied the art of parliamentary fencing. When he was at home he had frequent opportunities of hearing important debates at Westminster; and he heard them, not only with interest and enjoyment, but with close scientific attention. On one of these occasions Pitt, a youth whose abilities were as yet known only to his own family and to a small knot of college friends, was introduced on the steps of the throne in the House of Lords to Fox, his senior by eleven years, who was already the greatest debater, and one of the greatest orators, that had appeared in England. Fox used afterwards to relate that, as the discussion proceeded, Pitt repeatedly turned to him, and said, "But surely, Mr Fox, that might be met thus," or "Yes; but he lays himself open to this retort." What the particular criticisms were Fox had forgotten; but he said that he was much struck at the time by the precocity of a boy, not only the whole sitting, seemed to be thinking only how all the speeches on both sides could be answered.

He had not quite completed his nineteenth year when, on the 7th of April 1778, he attended his father to Westminster. A great debate was expected. It was known that France had recognized the independence of the United States. The duke of Richmond was about to declare his opinion that all thought of subjugating those states ought to be relinquished. Chatham had always maintained that the resistance of the colonies to the mother country was justifiable. But he conceived, very erroneously, that on the day on which their independence should be acknowledged the greatness of England would be at an end. Though sinking under the weight of years and infirmities, he determined, in spite of the entreaties of his family, to be in his place. His son supported him to a seat. The excitement and exertion were too much for the old man. In the very act of addressing the peers, he fell back in convulsions. A few weeks later his corpse was borne, with gloomy pomp, from the Painted Chamber to the Abbey. The favourite child and namesake of the deceased statesman followed the coffin as chief mourner, and saw it deposited in the transept where his own was destined to lie. His elder brother, now earl of Chatham, had too, sufficient, and barely sufficient, to support the dignity of the peerage. The other members of the family were poorly provided for. William had little more than £100 a year. It was necessary for him to follow a profession. He had already begun to "eat his terms." In the spring of 1780 he came of age. He then quitted Cambridge, was called to the bar, took chambers in Lincoln's Inn, and joined the western circuit. In the autumn of that year a general election took place; and he offered himself as a candidate for the university; but he was at the bottom of the poll. He was, however, at the request of an hereditary friend, the duke of Rutland, brought into parliament by Sir James Lowther for the borough of Appleby. The dangers of the country were at that time such as might well have disturbed a new member. The Army after army had been sent in vain against the rebellious colonies of North America. Meanwhile the house of Bourbon, humbled to the dust a few years before by the genius and vigour of Chatham, had seized the opportunity of revenge. France and Spain had united against England, and had recently been joined by Holland. The command of the Mediterranean had been for a time lost. The British flag had been scarcely able to maintain itself in the British Channel. The northern powers professed neutrality; but their neutrality had a menacing aspect. In the East, Hyder Ali had descended on the Carnatic, had destroyed the little army of Bailie, and had spread terror even to the ramparts of Fort St George. The discontent of Ireland threatened nothing less than civil war. In England the authority of Lord North's government had sunk to the
lowest point. The king and the House of Commons were alike unpopular. The cry for parliamentary reform was scarcely less loud and vehement than afterwards in 1830.

The Opposition consisted of two parties which had once been hostile to each other, but at this juncture seemed to act together with cordiality. The larger of these parties consisted of the great body of the Whig aristocracy, headed by Charles, marquess of Townshend. In the House of Commons the adherents of Rockingham were led by Fox, whose dissipated habits and ruined fortunes were the talk of the whole town, but whose commanding genius, and whose sweet, generous and affectionate disposition, extorted the admiration and love of those who most lamented the errors of his private life. Burke, superior to Fox in largeness of comprehension, in extent of knowledge, and in splendour of imagination, but less skilled in that kind of logic and in that kind of rhetoric which convince and persuade great assemblies, was willing to be the lieutenant of a young chief who might have been his son. A smaller section of the Opposition was composed of the old followers of Chatham. At their head was William, earl of Shelburne, distinguished both as a statesman and as a lover of science and letters. With him were leagued Lord Camden, who had formerly held the Great Seal, and whose integrity, ability and constitutional knowledge commanded the public respect; Barré, an eloquent and acrimonious declaimer; and Dunning, who had long held the first place at the English bar. It was to this party that Pitt was naturally attracted.

On the 26th of February 1781 he made his first speech in favour of Burke’s plan of economical reform. Fox stood up at the same moment, but instantly gave way. The lofty yet animated deportment of the young member, his perfect self-possession, the readiness with which he replied to the orators who had preceded him, the silver tones of his voice, the perfect structure of his unpremeditated sentences, astonished and delighted his hearers. Burke, moved even to tears, exclaimed, “It is not a chip of the old block; it is the old block itself.” “Pitt will be one of the first men in parliament,” said a member of the Opposition to Fox. “He is so already,” answered Fox, in whose nature envy had no place. Soon after this debate Pitt’s name was put up by Fox at Brookes’s Club. On two subsequent occasions during that session Pitt addressed the house, and on both fully sustained the reputation which he had acquired with his speeches against the ministerial ranks. From that night dates his connexion with Pitt, a connexion which soon became a close intimacy, and which lasted till it was dissolved by death. About a fortnight later Pitt spoke in the committee of supply on the army estimates. Symptoms of dissension had begun to appear on the treasury bench. Lord George Germaine, the secretary of state who was especially charged with the direction of the war in America, had held language not easily to be reconciled with declarations made by the first lord of the treasury. Pitt noticed the discrepancy with much force and keenness. Lord George and Lord North began to whisper together; and Welbore Ellis, an ancient placeman who had been drawing salary almost every quarter since the days of Henry Pelham, bent down between them to put in a word. Such interruptions sometimes discompose veteran speakers. Pitt stopped, and, looking at the group, said with admirable readiness, “I shall wait till Nestor has composed the dispute between Agamemnon and Achilles.” After several defeats, or victories hardly to be distinguished from defeats, the ministry resigned. The king, reluctantly and ungraciously, consented to accept Rockingham as first minister. Fox and Shelburne became secretaries of state. Lord John Cavendish, one of the most upright and honourable of men, was made chancellor of the exchequer. Thurlow, whose abilities and force of character had made him the dictator of the House of Lords, continued to hold the Great Seal. To Pitt was offered, through Shelburne, the vice-treasurership of Ireland, one of the easiest of the most highly paid places in the gift of the Crown; but the offer was without hesitation declined. The young statesman had resolved to accept no post which did not entitle him to a seat in the cabinet; and a few days later (March 1782) he announced that resolution in the House of Commons.

Pitt gave a general support to the administration of Rockingham, but omitted, in the meantime, no opportunity of courting that ultra-Whig party which the persecution of Wilkes and the Middlesex election had called into existence, and which the disastrous events of the war, and the triumph of republican principles in America, had made formidable both in numbers and in temper. He supported a motion for shortening the duration of parliaments. He made a motion for a committee to examine into the state of the representation, and, in the speech (May 7, 1782) by which that motion was introduced, avowed himself the enemy of the close boroughs, the strongholds of that corruption to which he attributed all the calamities of the nation, and which, as he phrased it in one of those exact and sonorous sentences of which he had a boundless command, had grown with the growth of England and strengthened with her strength, but had not diminished with her diminution or decayed with her decay. On this occasion he was supported by Fox. The motion was lost by only twenty votes in a house of more than three hundred members. The Reformers never again had so good a division till the year 1831.

The new administration was strong in abilities, and was more popular than any administration which had held office since the first year of George III., but was hated by the king, hesitatingly supported by the parliament, and torn by internal dissensions. It was all that Rockingham could do to keep the peace in his cabinet; and before the cabinet had existed three months Rockingham died. In an instant all was confusion. The adherents of Pitt and Fox were dissolved on the spot, and Lord Shelburne, now their chief. The king placed Shelburne at the head of the treasury. Fox, Lord John Cavendish, and Burke immediately resigned their offices; and the new prime minister was left to constitute a government out of very defective materials. It was necessary to find some member of the House of Commons who could confront the great orators of the Opposition; and Pitt alone had the eloquence and the courage which were required. He was offered the great place of chancellor of the exchequer and he accepted it (July 1782). He had scarcely completed his twenty-third year.

The parliament was speedily prorogued. During the recess a negotiation for peace which had been commenced under Rockingham was brought to a successful termination. England acknowledged the independence of her revolted colonies; and she ceded to her European enemies some places in the Mediterranean and in the Gulf of Mexico. But the terms which she obtained were quite as advantageous and honourable as the events of the war entitled her to expect, or as she was likely to obtain by persevering in a contest against immense odds. There is not the slightest reason to believe that Fox, if he had remained in office, would have hesitated one moment about concluding a treaty on such conditions. Unhappily Fox was, at this crisis, hurried by his passions into an error which made his genius and his country useless to his country. He saw that the great body of the House of Commons was divided into three parties—his own, that of North, and that of Shelburne; that none of those three parties was large enough to stand alone; that, therefore, unless two of them united there must be a miserably feeble administration.
or, more probably, a rapid succession of miserably feeble administrations, and this at a time when a strong government was essential to the prosperity and respectability of the nation. It was then necessary and right that there should be a coalition.

To every possible coalition there were objections. But of all possible coalitions that to which there were the fewest objections was undoubtedly a coalition between Shelburne and Fox. It would have been generally applauded by the followers of both. It might have been made without any sacrifice of public principle on the part of either. Unhappily, recent bickerings had left in the mind of Fox a profound dislike and distrust of Shelburne. Pitt attempted to mediate, and was authorized to invite Fox to return to the service of the Crown. "Is Lord Shelburne?" said Fox, "to remain prime minister?" Pitt answered in the affirmative. "It is impossible that I can act under him," said Fox. "Then negotiation is at an end," said Pitt; "for I cannot betray him." Thus the two statesmen parted. They were never again in a private room together. As Fox and his friends would not treat with Shelburne, nothing remained to them but to treat with North. That fatal coalition which is quartered by Carlyle "The Coalition" was formed. Not three quarters of a year had elapsed since Fox and Burke had threatened North with impeachment, and had described him night after night as the most arbitrary, the most corrupt, and the most incapable of ministers. They now allied themselves with him for the purpose of driving from office a statesman with whom they cannot be said to have differed as to any important question. Nor had they even the prudence and the patience to wait for some occasion on which they might, without inconsistency, have combined with their old enemies in opposition to the government. That nothing might be wanting to the scandal, the great orators who had, during seven years, thundered against the war determined to join with the authors of that war in passing a vote of censure on the peace.

The parliament met before Christmas 1782. But it was not till January 1783 that the preliminary treaties were signed. On the 17th of February they were taken into consideration by the House of Commons. There had been, during some days, floating rumours that Fox and North had coalesced; and the debate indicated but too clearly that those rumours were not unfounded. Pitt was suffering from indisposition—he did not rise till his own strength and that of his hearers were exhausted; and he was consequently less successful than on any former occasion. His admirers owned that his speech was feeble and petulant, and for far less honourable reasons than was usual with him. He attempted to confine himself to amusing theatrical audiences. This ignoble sarcasm gave Sheridan an opportunity of retorting with great felicity. "After what I have seen and heard to-night," he said, "I really feel strongly tempted to venture on a competition with so great an artist as Ben Jonson, and to bring on the stage a second Angry Boy." On a division, the address proposed by the supporters of the government was rejected by a majority of sixteen. But Pitt was not a man to be disheartened by a single failure, or to be put down by the most lively repartee. When, a few days later, the Opposition proposed a resolution directly censuring the treaties, he spoke with an eloquence, energy and vigour that raised his name to an elevation never attained before. To the coalition of Fox and North he alluded in language which drew forth tumultuous applause from his followers. "He," said, "this ill-omened and unnatural marriage be not yet consummated, I know of a just and lawful impeachment; and in the name of the public weal, I forbid the banns." The ministers were again left in a minority, and Shelburne consequently tendered his resignation (March 31, 1783). It was accepted; but the king struggled long and hard before he submitted to the terms dictated by Fox, whose faults he detested, and whose high spirit and powerful intellect he detested still more. The first place at the board of treasury was given to a man hated by Pitt; Pitt's hopes of a second ministry were steadily declined. The king, bitterly complaining of Pitt's faintheartedness, tried to break the coalition. Every art of seduction was practised on North, but in vain. During several weeks the country remained without a government. It was not till all devices had failed, and till the aspect of the House of Commons became threatening, that the king gave way. The duke of Portland was declared first lord of the treasury. Thurlow was dismissed. Fox and North became secretaries of state, with power ostensibly equal. But Fox was the real prime minister. The year was far advanced before the new arrangements were completed; and nothing very important was done during the remainder of the session. Pitt, now seated on the Opposition Bench, brought before the House the question of parliamentary reform a second time (May 7, 1783) under the consideration of the Commons. He proposed to add to the house at once a hundred county members and several members for metropolitan districts, and to enact that every borough of which an election committee should report that the majority of voters appeared to be corrupt should lose the franchise. The motion was rejected by 293 votes to 149.

After the prorogation Pitt visited the Continent for the first and last time. His travelling companion was one of his most intimate friends, William Wilberforce. That was the time of Anglomania in France; and at Paris the son of the great Chatham was absolutely hunted by men of letters and women of fashion, and forced, much against his will, into political disputation. One remarkable saying which dropped from him during this tour has been preserved. A French gentleman expressed some surprise at the immense influence which Fox, a man of pleasure, ruined by the dice-box and the turf, exercised over the English nation. "You have not," said Pitt, "been under the wand of the magician." In November 1783 the parliament met again. The government had irresistible strength in the House of Commons, and seemed to be scarcely less strong in the House of Lords, but was, in truth, surrounded on every side by dangers. The king was impatiently waiting for the moment at which he could emancipate himself from a yoke which galled him so severely that he had more than once seriously thought of retiring to Hanover; and the king was scarcely more eager for a change than the nation. Fox and North had committed a fatal error. They ought to have known that coalitions between parties which have long been hostile can succeed only when the wish for coalition pervades the lower ranks of both. At the beginning of 1783 North had been the recognized head of the old Tory party, which, though for a moment proscribed by the disastrous issue of the American war, was still a great power in the state. Fox had, on the other hand, been the idol of the Whigs, and of the whole body of Protestant dissenters. The coalition at once alienated the most zealous Tories from North and the most zealous Whigs from Fox. Two great multitudes were at once left without any head, and both at once turned their eyes on Pitt. One party saw in him the only man who could rescue the king; the other saw in him the only man who could purify the parliament. He was supported on one side by Archbishop Markham, the preacher of divine right, and by Jenkinson, the captain of the praetorian band of the king's friends; on the other side by Jebb and Priestley, Sawbridge and Cartwright, Jack Wilkes and Horne Tooke. On the benches of the House of Commons, the friends of Pitt, being in a majority, were not only the loudest, but the most effective. The king, therefore, was at last determined to try a coalition. And that any statesman would venture to brave such a majority was thought impossible. No prince of the Hanoverian line had ever, under any provocation, ventured to appeal from the representative body to the constituent body. The ministers, therefore, notwithstanding the sullen looks and muttered words of displeasure with which their suggestions were received in the closet, notwithstanding the roar of obloquy which was rising louder and louder every day from every corner of the island, thought themselves secure. Such was their confidence in their strength that, as soon as the parliament had met, they brought forward a singularly bold and original plan for the government of India. Pitt's dream, to which he had been brought and by Pitt's friends called the "Eastern project," was to leave to the East India Company the East Indies. The plan was for the next year to be submitted to seven commissioners, who were to be
named by parliament, and were not to be removable at the
pleasure of the Crown. Earl Fitzwilliam, the most intimate
personal friend of Fox, was to be chairman of this board, and
the eldest son of North was to be one of the members.

As soon as the outlines of the scheme were known all the
hatred which the coalition had excited burst forth with an
astounding explosion. Burke, who, whether right
or wrong, decided to join the new administration, thought in
at least the merit of looking at the subject in the
right point of view, vainly reminded his hearers of that
mighty population whose daily rice might depend on a
vote of the British parliament. He spoke with even more
than his wonted power of thought and language, about the
desolation of Rohilcund, about the spoliation of Benares, about
the evil policy which had suffered the tanks of the Carnatic to go
to ruin; but he could scarcely obtain a hearing. The contending
parties, to their shame it must be said, would listen to none but
English topics. Out of doors the cry against the ministry was
almost universal. Town and country were united. Corpora-
tions exclaimed against the violation of the charter of the
greatest corporation in the realm. Tories and democrats
joined in pronouncing the proposed board an unconstitution-
Al body. It was to consist of Fox's nominees. The effect of his
bill was to give, not to the Crown, but to him personally, whether
in office or in opposition, an enormous power, a patronage
sufficient to counterbalance the patronage of the treasury and of
the admiralty, and to decide the elections for fifty boroughs.
He knew, it was said, that he was hateful alike to king and
people; and he had devised a plan which would make him
independent of both. Some nicknamed him Cromwell, and
some Carlo Khan. Wilberforce, with his usual felicity of
expression, and with very unusual bitterness of feeling, described
the scheme as the genuine offspring of the coalition, as marked
with the features of both its parents, the corruption of one and
the violence of the other. In spite of all opposition, however,
the bill was supported in every stage by great majorities, was
rapidly passed, and was sent up to the Lords. To the general
astonishment, when the second reading was moved in the
upper house, the Opposition proposed an adjournment, and
escorted by eighty-seven votes to seventy-nine. The cause of this
strange turn of fortune was soon known. Pitt's cousin
Earl Temple, had been in the royal closet, and had there been
authorized to let it be known that his majesty would consider all
who voted for the bill as his enemies. The ignominious
commission was performed, and instantly a troop of lords of
the bedchamber, of bishops who wished to be translated, and
of Scotch peers who wished to be re-elected, made
taste to change sides. On a later day the Lords
rejected the bill. Fox and North were immediately
directed to send their seals to the palace by their under-secret-
taries; and Pitt was appointed first lord of the treasury and
chancellor of the exchequer (December 1783).

The general opinion was that there would be an immediate
dissolution. But Pitt wisely determined to give the public
feeling time to gather strength. On this point he differed from his
kinsman the Duke of Northumberland. The consequence was that Temple, who
had been appointed one of the secretaries of state, resigned his
office forty-eight hours after he had accepted it, and thus relieved
the new government from a great load of unpopularity; for all
men of sense and honour, however strong might be their dislike of
the India Bill, disapproved of the manner in which that bill
had been thrown out. The fame of the young prime minister
preserved its whiteness. He could declare with perfect truth
that, if unconstitutional machinations had been employed, he
had been no party to them.

He was, however, surrounded by difficulties and dangers.
In the House of Lords, indeed, he had a majority; nor could any
orator of the Opposition in that assembly be considered as
in fact his foe. The consequence was that Temple, who
had been appointed the son of his old friend Chatham.
But in the other house there was not a single eminent speaker
among the official men who sat round Pitt. His most useful
assistant was Dundas, who, though he had not eloquence, had
sense, knowledge, readiness and boldness. On the opposite
benches was a powerful majority, led by Fox, who was supported
by Burke, North and Sheridan. The heart of the young minis-
ter, stout as it was, almost died within him. But, whatever
his internal emotions might be, his language and deportment
indicated nothing but unconquerable firmness and haughty
confidence in his own powers. His contest against the House of
Commons lasted from the 17th of December 1783 to the
division of March 1784. In sixteen divisions the Opposition triumphed.
Again and again the king was requested to dismiss his ministers;
but he was determined to go to Germany rather than yield.
Pitt's resolution never wavered. The cry of the nation in his
favour became vehement and almost furious. Addresses
assuring him of public support came up daily from every part of
the kingdom. The freedom of the city of London was presented
to him in a gold box. He was sumptuously feasted in Grocers' Hall;
and the shopkeepers of the Strand and Fleet Street illuminated
their houses in his honour. These things could not
but produce an effect within the walls of parliament. The
ranks of the majority began to waver; a few passed over to the
enemy; some skulked away; many were for capitulating while
it was still possible to capitulate with the honours of war.
Negotiations were opened with the view of forming an admin-
istration on a wide basis, but they had scarcely been opened when
they were closed. The Opposition demanded, as a preliminary
article of the treaty, that Pitt should resign the treasury; and
with this demand Pitt steadfastly refused to comply. While
the contest was raging, the clerkship of the Pells, a sinecure place
for life, worth three thousand a year, and tenable with a seat
in the House of Commons, became vacant. The appointment
was with the chancellor of the exchequer; nobody doubted that
he would appoint himself, and nobody could have blamed him
if he had done so; for such sinecure offices had always been
defended on the ground that they enabled a few men of eminent
abilities and small incomes to live without any profession, and
to devote themselves to the service of the state. Pitt, in spite
of the remonstrances of his friends, gave the Pells to his father's
old adherent, Colonel Barré, a man distinguished by talent and
elegance, but poor and afflicted with blindness. By this
arrangement a pension which the Rockingham administration
had granted to Barré was saved to the public. Pitt had his
reward. No minister was ever more rancourously labelled; but
Pitt the politician, who in all the allurements of the whole
millions were passing through his hands, when the wealthiest
magistrates of the realm were soliciting him for marquises and
garters, his bitterest enemies did not dare to accuse him of
touching unlawful gain.

At length the hard-fought fight ended. A final remon-
strance, drawn up by Burke with admirable skill, was carried
on the 8th of March by a single vote in a full house.
The supplies had been voted; the Mutiny Bill had been passed;
and the parliament was dissolved. The popular constituent
bodies all over the country were in general enthusiastic on the
side of the new government. A hundred and sixty of the
supporters of the coalition, who had signed the treaty, had
in the act of signing the treaty himself came in at the head of the poll
for the university of Cambridge. Wilberforce was elected knight of the great
shire of York, in opposition to the whole influence of the Fitz-
williams, Cavendishes, DUNDASES and Saviles. In the midst
of such triumphs Pitt completed his twenty-fifth year. He
was now the greatest subject that England had seen during
many generations. He dominated absolutely over the cabinet,
and was the favourite at once of the sovereign, of the parliament
and of the nation. His father had never been so powerful, nor
Walpole, nor Marlborough.

Pitt's first administration (1784-1801) lasted seventeen
years. That long period was divided by a strongly marked line into
two distinct exactly equal parts. The first part, Pitt's First
administration ended and the second began in the autumn of 1792. Admis-
istration. Throughout both parts Pitt displayed in the highest degree the talents of a parliamentary leader. During the first
part he was fortunate and in many respects a skilful administrator. With the difficulties which he had to encounter during the second part he was altogether incapable of contending; but his eloquence and his perfect mastery of the tactics of the House of Commons concealed his incapacity from the multitude.

The eight years which followed the general election of 1784 were as tranquil and prosperous as any eight years in the whole history of England. Her trade increased. Her manufactures flourished. Her exchequer was full to overflowing. Very idle apprehensions were generally entertained that the public laws, though much less than a third of the debt which we now bear with ease, would be found too heavy for the strength of the nation. But Pitt succeeded in persuading first himself and then the whole nation, his opponents included, that a new sinking fund, which, so far as it differed from former sinking funds, differed for the worse, would, by virtue of some mysterious power of propagation belonging to money, put into the pocket of the public creditor great sums not taken out of the pocket of the tax-payer. The minister was almost universally extolled as the greatest of financiers. Meanwhile both the branches of the house of Bourbon found that England was as formidable an antagonist as she had ever been. France had formed a plan for reducing Holland to vassalage. But England interposed, and France receded. Spain interrupted by violence the trade of the English merchants with the regions near the Oregon. But England armed, and Spain receded. Within the island there was profound tranquillity. The king was, for the first time, popular. From the day on which Pitt was placed at the head of affairs there was an end of secret influence. Any attempt to undermine him at court, any mutinous movement among his followers in the House of Commons, was certain to be at once put down. He had only to tender his resignation and he could dictate his own terms. For he, and he alone, stood between the king and the coalition. The nation loudly applauded the king for having the wisdom to repose entire confidence in so excellent a minister. His people heartily prayed that he might long reign over them; and they prayed more heartily because his virtues were set off to the best advantage by the vices and follies of the prince of Wales, who lived in close intimacy with the chiefs of the Opposition.

How strong this feeling was in the public mind appeared signally on one great occasion. In the autumn of 1788 the king became insane. The Opposition, eager for office, committed the great error of entertaining that the heir apparent had, by the fundamental laws of England, a right to be regent with the full powers of royalty. Pitt, on the other hand, maintained it to be the constitutional doctrine that when a sovereign is, by reason of infancy, disease or absence, incapable of exercising the regal functions, it belongs to the estates of the realm to determine who shall be the viceregent, and with what portion of the executive authority such viceregent shall be entrusted. A long and violent contest followed, in which Pitt was supported by the great body of the people with as much enthusiasm as during the first months of his administration. Tories with one voice opposed him for the benefit of a regent, and an unhappy sovereign against a dishonourable and an undignified union of interests between the Whigs and the ministry. Pitt, by his declarations and his conduct, came near to ruin his administration. The king, in a way that astonished even his most sanguine friends, became insane, and in May 1789 restored Pitt to the office of first minister. The Minister, the Opposition, the Whigs applauded him for asserting the authority of parliaments and the principles of the Revolution, in opposition to a doctrine which seemed to have too much affinity with the servile theory of indefeasible hereditary right. The middle class, always zealous on the side of decency and the domestic virtues, looked forward with dismay to a reign resembling that of Charles II. That the prince of Wales must be regent nobody ventured to deny. But he and his friends were so unpopular that Pitt could, with general approbation, propose to limit the powers of the regent by restrictions to which it would have been impossible to submit without a year, and all the prince would withdraw from the country. The nation, interested men, fully expecting a change of administration, went over to the Opposition. But the majority, purified by these desertions, closed its ranks, and presented a more firm array than ever to the enemy. In every division Pitt was victorious. When at length, after a stormy interregnum of three months, it was announced, on the very eve of the inauguration of the regent, that the king was himself again, the nation was wild with delight. Pitt with difficulty escaped from the tumultuous kindness of an innumerable multitude which insisted on drawing his coach from St Paul's Churchyard to Downing Street. This was the moment at which his fame and fortune may be said to have reached the zenith. His influence in the closet was as great as that of Carr or Villiers had been. Army and dominion over the parliament was more absolute than that of Walpole or Pelham had been. He was at the same time as high in the favour of the populace as ever Wilkes or Sacheverell had been. But now the tide was on the turn. Only ten days after the triumphant procession to St Paul's, the states-general of France, after an interval of a hundred and seventy-four years, met at Versailles.

The nature of the great Revolution which followed was long very imperfectly understood in England. Burke saw much further than any of his contemporaries; but whatever his sagacity deserved was refracted and discoloured by his passions and his imagination. More than three years elapsed before the principles of the English administration underwent any material change. Nothing could as yet be milder or more strictly constitutional than the minister's domestic policy. Not a single act indicating an arbitrary temper or a jealousy of the people could be imputed to him. In office, Pitt had redeemed the pledges which he had, at his entrance into public life, given to the supporters of parliamentary reform. He had, in 1785, brought forward a judicious plan for the representative system, and had prevailed on the king, not only to refrain from talking against that plan, but to recommend it to the houses in a speech from the throne. This attempt failed; but there can be little doubt that, if the French Revolution had not produced a violent reaction of public feeling, Pitt would have performed, with little difficulty and no danger, that great work which, at a later period, Lord Grey could accomplish only by means which for a time loosened the very foundations of the commonswealth. When the atrocities of the slave trade were first brought under the consideration of parliament no abolitionist was more zealous than Pitt. A humane bill, which mitigated the horrors of the middle passage, was, in 1788, carried by the eloquence and determined spirit of Pitt, in spite of the opposition of some of his own colleagues. In 1791 he concurred with Fox in maintaining the sound constitutional doctrine that an impeachment is not terminated by a dissolution. In the course of the same year the two great rivals contended side by side in a far more important cause. They are fairly entitled to divide the high honour of having added to the statute-book the inestimable law which places the liberty of the press under the protection of juries. On one occasion, and one alone, Pitt, during the first half of his long administration, acted in a manner unworthy of an enlightened Whig. In the debate on the Test Act he stooped to gratify the master whom he served, the university which he represented, and the great body of clergymen and country gentlemen on whose support he rested, by talking, with little heartiness or zeal, the language of a Tory. With this single exception, his conduct from the end of 1783 to the middle of 1792 was that of an honest friend of civil and religious liberty.

Nor did anything, during that period, indicate that he loved war, or harboured any malevolent feeling against any neighbouring nation. Those French writers who have represented him as a Hannibal sworn in childhood by his father to bear eternal hatred to France, as having, by mysterious intrigues and lavish bribes, instigated the leading Jacobins to commit those excesses which dishonoured the Revolution, as having been the real

1 The speech with which the king opened the session of 1785 concluded with an assurance that his majesty would heartily concur in every measure which could tend to secure the true principles of the constitution. These words were at the time understood to refer to Pitt's Reform Bill.
author of the first coalition, know nothing of his character or of his history. So far was he from being a deadly enemy to France that his laudable attempts to bring about a closer connexion with that country by means of a wise and liberal treaty of commerce brought on him the severe censure of the Opposition. He was told in the House of Commons that he was a degenerate son, and that his partiality for the hereditary foes of our island was enough to make his great father’s bones stir under the pavement of the Abbey.

And this man, whose name, if he had been so fortunate as to die in 1792, would have been associated with peace, with freedom, with pitiful anthems, with temperate reform, with mild and constitutional administration, lived to associate his name with arbitrary government, with harsh laws harshly executed, with alien bills, with gagging bills, with suspensions of the Habeus Corpus Act, with cruel punishments inflicted on some political agitators, with unjustifiable prosecutions instigated against others and with the most costly and most sanguinary wars of modern times. He lived to be held up to obloquy as the stern oppressor of England and the indefatigable disturber of Europe. Poets, contrasting his earlier with his later years, likened him sometimes to the apostle who kissed in order to betray, and sometimes to the evil angels who knew not their first estate.

By the French press and the French tribune, he was disdained and every calamity that afflicted France was ascribed to the monster Pitt and his guineas. While the Jacobins were dominant it was he who had corrupted the Girondine, who had raised Lyons and Bordeaux against the Convention, who had suborned Paris to assassinate Lepelletier, and Cecilia Regnault to assassinate Robespierre. When the Thermidorian reaction came, all the atrocities of the Reign of Terror were imputed to him. Collot D’Herbois and Fouquier Tinville had been his pensioners. It was he who had hired the murderers of September, who had dictated the pamphlets of Marat and the carmagnoles of Barère, who had paid Lebon to deluge Arras with blood and Carrier to choke the Loire with corpses. The truth is that he liked neither war nor arbitrary government. He was a lover of peace and freedom, driven, by a stress against which it was hardly possible for any will or any intellect to struggle, out of the course to which his inclinations pointed, and for which his abilities and acquisitions fitted him, and forced into a policy repugnant to his feelings and unsuited to his talents.

Between the spring of 1789 and the close of 1792 the public mind of England underwent a great change. If the change of Pitt’s sentiments attracted peculiar notice, it was not because he changed more than his neighbours, or because he changed less than most of them, but because his position was far more conspicuous than theirs, because he was, till Bonaparte appeared, the individual who filled the greatest space in the eyes of the-inhabitants of the civilized world. During a short time the nation, and Pitt as one of the nation, looked with interest and approbation on the French Revolution. But soon vast confiscations, the violent sweeping away of ancient institutions, the domination of clubs, the barbarities of mobs maddened by famine and hatred, produced a reaction. The court, the nobility, the gentry, the clergy, the manufacturers, the merchants, in short nineteen-twentieths of those who had good rooves over their heads and good coasts on their backs, became eager intolerant Antijacobins. This feeling was at least as strong among the minister’s adversaries as among his supporters. Fox in vain attempted to restrain his followers. All his genius, all his vast personal influence, could not prevent them from rising up against him in general mutiny. Burke set the example of revolt; and Burke was in no long time joined by Portland, Spencer, Fitzwilliam, Loughborough, Carlisle, Malmsbury, Windham, Elliot. In the House of Commons the followers of the great Whig statesman and orator diminished from about a hundred and sixty to fifty. In the House of Lords he had but ten or twelve adherents left. There can be no doubt that there would have been a similar mutiny on the ministerial benches if Pitt had obstinately resisted the general wish. Pressed at once by his master and by his colleagues, by old friends and by old opponents, he abandoned, slowly and reluctantly, the policy which was dear to his heart. He laboured hard to avert the European war. When the European war broke out he still flattered himself that it would not be necessary for this country to take either side. In the spring of 1792 he congratulated the parliament on the prospect of long and profound peace, and proved his sincerity by proposing large remissions of taxation. Down to the end of that year he continued to cherish the hope that England might be able to preserve neutrality. But the passions which raged on both sides of the Channel were not to be restrained. The republicans who ruled France were inflamed by a fanaticism resembling that of the Mussulmans, who, with their swords and their heads in their hands, went forth conquering and converting, eastward to the Bosphorus and westward to the Pillars of Hercules. The higher and middle classes of England were animated by zeal not less fiery than that of the crusaders who raised the cry of Deus vult at Clermont. The impulse which drove the two nations to a collision was not to be arrested by the abilities or by the authority of any single man. As Pitt was in front of his fellows, and towered high above them, he seemed to lead them. But in fact he was violently pushed on by them, and, had he held back a little more than he did, would have been thrust out of their way like Napoleon and deposed under the coup d’état.

He yielded to the current; and from that day his misfortunes began. The truth is that there were only two consistent courses before him. Since he did not choose to oppose himself, side by side with Fox, to the public feeling, he should have taken the advice of Burke, and should have availed himself of that feeling to the full extent. If it was impossible to preserve peace, he should have adopted the only policy which should lead to victory. He should have proclaimed a holy war for religion, morality, property, order, public law, and should have thus opposed to the Jacobins an energy equal to their own. Unhappily he tried to find a middle path; and he found one which united all that was worst in both extremes. He went to war; but he could not understand the peculiar character of that war. He was obstinately blind to the plain fact that he was contending against a state which was also a sect, and that a new quarrel between England and France was of quite a different kind from the old quarrels about colonies in America and fortresses in the Netherlands. It was pitiable to hear him, year after year, proving to an admiring audience that the wicked republic was exhausted, that she could not hold out, that her credit was gone, that her assignats were not worth more than the paper of which they were made—as if credit was the Kurgan in a gondolier’s hand. The principle was rapine, as if Albin could not turn Italy into a desert by which he had negotiated a loan at 5%, as if the exchequer bills of Atilla had been at par. It was impossible that a man who so completely mistook the nature of a contest could carry on that contest successfully. Great as Pitt’s abilities were, his military administration was that of a driveller. In such an emergency, and with such means, such a statesman as Richelieu, as Louvois, as Chatham, as Wellesley, would have created in a few months one of the finest armies in the world, and would soon have discovered and brought forward generals worthy to command such an army. Germany might have been saved by another Blenheim; Flanders recovered by another Ramillies; another Ponthieu might have delivered the Royalist and Catholic provinces of France from a yoke which they abhorred, and might have spread terror even to the barriers of Paris. But the fact is that, after eight years of war, after a vast destruction of life, after an expenditure of wealth far exceeding the expenditure of the American War, of the Seven Years’ War, of the War of the Austrian Succession and of the War of the Spanish Succession united, the English army under Pitt was the laughing-stock of all Europe. It could not boast of one single brilliant exploit. It had never shown itself on the Continent but to be beaten, chased, forced to re-embark or forced to capitulate. To take some sugar island in the West Indies, to scatter some mob of half-naked Irish peasants—such were the most splendid victories.
PITT, WILLIAM

won by the British troops under Pitt's auspices. The English navy no mismanagement could ruin. But during a long period whatever mismanagement could do was done. The earl of Chatham, without a single qualification for high public trust, was made, by fraternal partiality, first lord of the admiralty, and was kept in that great post during the long years of peace in which the greatness of the navy depended on the efficiency of the fleet. Fortunately he was succeeded by George, Earl Spencer, one of those chiefs of the Whig party who, in the great schism caused by the French Revolution, had followed Burke. Lord Spencer, though inferior to many of his colleagues as an orator, was decidedly the best administrator among them. To him it was owing that a long and gloomy succession of days of fasting, and most emphatically of humiliation, was interrupted, twice in the short space of eleven months, by days of thanksgiving for great victories.

It may seem paradoxical to say that the incapacity which Pitt showed in all that related to the conduct of the war, is, in some sense, the most decisive proof that he was a man of very extraordinary abilities. Yet this is the simple truth. While his schemes were confounded, while his predictions were falsified, while the coalitions which he had laboured to form were falling to pieces, while the expeditions which he had sent forth at enormous cost were ending in rout and disgrace, while the enemy and the enemy against whom he was feebly contending was subjugating Flanders and Brabant, the elector of Mainz and the elector of Trèves, Holland, Piedmont, Liguria, Lombardy, his authority over the House of Commons was constantly becoming more and more absolute. There was his empire.

There were his victories—his Lodi and his Arcola, his Rivoli and his Marengo. Of the great party which had contended against him during the first eight years of his administration more than one-half now marched under his standard, with his old competitor the duke of Portland at their head; and the rest had, after many vain struggles, quitted the field in despair. Session followed session with scarcely a single division. In the eventful year 1799 the largest minority that could be mustered against the government was twenty-five.

In Pitt's domestic policy there was at this time assuredly no want of vigour. While he offered to French Jacobinism a resistance so fierce that it only encouraged him, and while he wished states to be formed, but not formed for office.

Jachinism with a strong hand. The Habeas Corpus Act was repeatedly suspended. Public meetings were placed under severe restraints. The government obtained from parliament power to send out of the country aliens who were suspected of evil designs; and that power was not suffered to be idle. Writers who propounded doctrines adverse to monarchy and aristocracy were proscribed and punished without mercy. The old laws of Scotland against sedition, laws which were considered by Englishmen as barbarous, and which a succession of governments had suffered to rust, were now turned up and sharpened anew. Men of cultivated minds and polished manners were, for offences which at Westminster would have been treated as mere misdemeanours, sent to hord with felons at Botany Bay. Some reformers, whose opinions were extravagant, and whose language was intemperate, but who had never dreamed of subverting the government by physical force, were indicted for high treason, and were saved from the gallows only by the righteous verdicts of juries.

One part only of Pitt's conduct during the last eight years of the 18th century deserves high praise. He was the first English minister who formed great designs for the benefit of Ireland. Had he been able to do all that he wished, he would have been the wisest man, and his policy would have averted the rebellion of 1798. But the difficulties which he encountered were great, perhaps insurmountable; and the Roman Catholics were, rather by his misfortune than by his fault, thrown into the hands of Jacobsen. There was a third great rising of the Irishry against the Englishry, a rising not less formidable than the risings of 1641 and 1688. The Englishly remained victorious; and it was necessary for Pitt, as it had been necessary for Oliver Cromwell and William of Orange before him, to consider how the victory should be used. He determined to make Ireland one kingdom with England, and, at the same time, to relieve the Roman Catholic laity from civil disabilities, and to grant a public maintenance to the Roman Catholic clergy. Had he been able to carry these noble designs into effect the union would have been a union indeed. But Pitt could execute only one-half of what he had projected. He succeeded in obtaining the consent of the parliaments of both kingdoms to the union; but that reconciliation of races and sects without which the union could exist only in name was not accomplished.

The king imagined that his coronation oath bound him to refuse his assent to any bill for relieving Roman Catholics from civil disabilities. Dundas tried to explain the matter, but was told to keep his Scotch metaphysics to himself. Pitt and Pitt's ablest colleagues resigned their offices (March 14, 1801).

It was necessary that the king should make a new arrangement. But by this time his anger and distress had brought back the malady which had, many years before, incapacitated him for the discharge of his functions. He actually assembled his family, read the coronation oath to them, and told them that, if he broke it, the crown would immediately pass to the house of Savoy. It was not until after an interregnum of several weeks that he regained the full use of his small faculties, and that a ministry after his own heart was at length formed. In an age pre-eminently fruitful of parliamentary talents, a cabinet was formed containing hardly a single man who in parliamentary talents could be considered as even of the second rate. Henry Addington was at the head of the treasury. He had been, early, indeed, an hereditary friend of Pitt, and had by Pitt's influence been placed, while still a young man, in the chair of the House of Commons. He was universally admitted to have been the best Speaker that had sat in that chair since the retirement of Onslow. But nature had not bestowed on him very vigorous faculties; and the highly respectable situation which he long occupied with honour had rather unfitted than fitted him for the discharge of his new duties. Nevertheless, during many months, his power seemed to stand firm. The nation was put into high good humour by a peace with France. The enthusiasm with which the upper and middle classes had rushed into the war as a national effort, which the peace restored. Jacobinism was no longer formidable. Everywhere there was a strong reaction against what was called the atheistical and anarchical philosophy of the 18th century. Bonaparte, now first consul, was busied in constructing out of the ruins of old institutions a new ecclesiastical establishment and a new order of knighthood. The treaty of Amiens was therefore hailed by the great body of the English people with extravagant joy. The popularity of the minister was for the moment immense. His want of parliamentary ability was, as yet, of little consequence; for he had scarcely any adversary to encounter. The old Opposition, delighted by the peace, regarded him with favour. A new Opposition had indeed been formed by some of the late ministers, and was led by Grenville in the House of Lords and by Windham in the House of Commons. But the new Opposition could scarcely muster ten votes, and was regarded with no favour by the country.

On Pitt the ministers relied as on their firmest support. He had not, like some of his colleagues, retired in anger. He had expressed the greatest respect for the conscientious scruple which had taken possession of the royal mind; and he had promised his successors all the help in his power. But it was hardly possible that this union should be durable. Pitt, conscious of superior powers, imagined that the place which he had quitted was now occupied by a mere puppet which he had set up, which he was to govern while he suffered it to remain, and which he was to fling aside as soon as he wished to resume his old position. Nor was it long before he began to pine for the power which he had relinquished. Addington, on the other hand, was by no means inclined to descend from his high position. He took his elevation quite seriously, attributed it
to his own merit, and considered himself as one of the great triumvirs of English statesmen, worthy to make a third with Pitt and Fox. Meanwhile Pitt's most intimate friends exerted themselves to effect a change of ministry. His favourite disciple, George Canning, was indefatigable. He spoke; he wrote; he intrigued; he tried to induce a large number of the supporters of the government to sign a round robin desiring a change; he made game of Addington and of Addington's relations in a succession of lively pasquinades. The minister's partisans retorted with equal acrimony, if not with equal vivacity. Pitt could keep out of the affray only by keeping out of politics altogether; and this it soon became impossible for him to do. The treaty of Amiens had scarcely been signed when the restless and ambitious ministers of the First Consul convinced the great body of the English people that they could eagerly welcomed only a precocious armistice. As it became clearer and clearer that a war for the dignity, the independence, the very existence of the nation was at hand, men looked with increasing uneasiness on the weak and languid cabinet which would have to contend against an enemy who united more than the power of Louis the Great to more than the genius of Frederick the Great. They imagined that Pitt was the only statesman who could cope with Bonaparte. This feeling was nowhere stronger than among Addington's own colleagues. The pressure put on him was so strong that he could not help yielding to it. His first proposition was that some insignificant nobleman should be first lord of the treasury and nominal head of the administration, and that the real power should be divided between Pitt and himself, who were to be secretaries of state. Pitt, as might have been expected, refused even to discuss such a scheme, and talked of it with bitter mirth. "Which secretarysty was offered to you?" his friend Wilberforce asked. "Really," said Pitt, "I had not the curiosity to inquire." Addington was frightened into bidding higher. He offered to resign the treasury to Pitt on condition that there should be no extensive change in the government. But Pitt would not listen. His first advice was to withdraw. Then came a dispute such as often arises after negotiations orally conducted, even when the negotiators are men of strict honour. Pitt gave one account of what had passed; Addington gave another; and, though the discrepancies were not such as necessarily implied any intentional violation of truth on either side, both were greatly exasperated.

Meanwhile the quarrel with the First Consul had to come to a crisis. On the 16th of May 1803 the king sent a message calling on the House of Commons to support him in withstanding the ambitious and encroaching policy of France; and on the 22nd the house took the message into consideration.

Pitt had now been living many months in retirement. There had been a general election since he had spoken in parliament, and there were two hundred members who had never heard him. It was known that on this occasion he would be in his place, and curiosity was wound up to the highest point. Unfortunately, the shorthand writers were, in consequence of some mistake, shut out on that day from the gallery, so that the newspapers contained only a very meagre report of the proceedings. But several accounts of what passed are extant; and of those accounts the most interesting is contained in an unpublished letter written by a very young member, John William Ward, afterwards earl of Dudley. When Pitt rose he was received with loud cheering. At every pause in his speech there was a burst of applause. The oration is said to have been one of the most animated and magnificent ever heard in parliament. "Pitt's speech," Fox wrote a few days later, "was admired very much, and very truly. I think it was the best he ever made in that style." The debate was adjourned; and on the second night Fox replied to it in an oration which, as the most zealous Pittites were forced to acknowledge, left the palm of eloquence doubtful. Addington made a pitiable appearance between the two great rivals; and it was observed that Pitt, while exhorting the Commons to stand resolutely by the executive government against France, said not a word indicating esteem or friendship for the prime minister.

War was speedily declared. The First Consul threatened to invade England at the head of the conquerors of Belgium and Italy, and formed a great camp near the Straits of Dover. On the other side of those straits the whole British population was ready to rise up as one man in defence of the soil. In the spring of 1804 it became evident that the weakest of ministries would have to defend itself against the strongest of Oppositions, an Opposition made up of three Oppositions, each of which would, separately, have been formidable from ability, and which, when united, were also formidable from number. It was necessary to give way; the ministry was dissolved, and the task of performing a government was entrusted (May 1804) to Pitt. Pitt was of opinion that there was now an opportunity, such as had never before offered itself, and such as might never offer itself again, of uniting in the public service, on honourable terms, all the eminent talents of the kingdom. Pitt's Second Administration was not to be a mere Act of Consolation. He proposed to assign a share of power little inferior to that of his predecessor to his own. The plan was excellent; but the king would not hear of it. Dull, obstinate, unforgiving, and at that time half mad, he positively refused to admit Fox into his service. In an evil hour Pitt yielded. All that was left was to construct a government out of the wreck of Addington's administration. The small circle of Pitt's personal retainers furnished him with a very few useful assistants, particularly Dundas (who had been created Viscount Melville), Lord Harrowby and Canning.

Such was the inauspicious manner in which Pitt entered on his second administration (May 12, 1804). The whole history of that administration was of a piece with the commencement. Almost every month brought some new disaster or disgrace. To the war with France was soon added a war with Spain. The opponents of the ministry were numerous, able and active. His most useful coadjutors he soon lost. Sickness deprived them of the help of Lord Harrowby. It was discovered that Lord Melville had been guilty of highly culpable laxity in transactions relating to public money. He was censured by the House of Commons, driven from office, ejected from the privy council and impeached of high crimes and misdemeanours. The blow fell heavy on Pitt. His difficulties compelled him to resort to various expedients. At one time Addington was persuaded to accept office with a peereage; but he brought no additional strength to the government. While he remained in place he was jealous and punctilious; and he soon retired again. At another time Pitt renewed his efforts to overcome his master's aversion. Fox hoped that the task of perfidy was gradually giving way. But, meanwhile, it was impossible for the minister to conceal from the public eye the decay of his health and the constant anxiety which gnawed at his heart. All who passed him in the park, all who had interviews with him in Downing Street, saw misery written in his face. The peculiar look which he wore during the last months of his life was often pathetically described by Wilberforce, who used to call it the Austerlitz look.

Still the vigour of Pitt's intellectual faculties and the intrepid haughtiness of his spirit remained unaltered. He had staked everything on a great venture. He had succeeded in forming another mighty coalition against the French ascendency. The united forces of Austria, Russia and England might, he hoped, oppose an insurmountable barrier to the ambition of the common enemy. But the genius and energy of Napoleon prevailed. While the English troops were preparing to embark for Germany, while the Russian troops were slowly coming up from Poland, he, with rapidity unprecedented in modern war, moved a hundred thousand men from the shores of the ocean to the Black Forest, and compelled a great Austrian army to surrender at Ulm. To the first faint rumours of this calamity Pitt would give no credit. He was irritated by the alarms of those around him. "Do not believe a word of it," he said; "it is all a fiction." The next day he received a Dutch newspaper containing the
PITT, WILLIAM

capitulation. He knew no Dutch. It was Sunday, and the public offices were shut. He carried the paper to Lord Malmesbury, who had been minister in Holland; and Lord Malmesbury translated it. Pitt tried to bear up, but the shock was too great; and he went away with dead in his face. The news of the battle of Trafalgar arrived four days later, and seemed for a moment to revive him. Forty-eight hours after that most glorious and most mournful of victories had been announced to the country came the Lord Mayor's Day; and Pitt dined at Guildhall. His popularity had declined. But on this occasion the multitude, greatly excited by the recent tidings, welcomed him enthusiastically, took off his horses in Cheapside, and drew his carriage up King Street. When his health was drunk, he returned thanks in two or three of those stately sentences of which he had a boundless command. Several of those who heard him laid up his words in their hearts; for they were the last words that he ever uttered in public:

"Let us hope that England, having saved herself by her energy, may save Europe by her example."

This was but a momentary rally. Austerlitz soon completed what Ulm had begun. Early in December Pitt had retired to Bath, in the hope that he might there gather strength for the approaching session. While he was languishing there on his sofa arrived the news that a decisive battle had been fought and lost in Moravia, that the coalition was dissolved, that the Continent was at the feet of France. He sank down under the blow. Ten days later he was so emaciated that his most intimate friends hardly knew him. He came up from Bath by slow journeys, and on the 11th of January 1806 reached his villa at Putney. Parliament was to meet on the 21st. On the 20th to be the parliamentary dinner at the house of the first lord of the treasury in Downing Street; and the cards were already issued. But the days of the great minister were numbered. On the day on which he was carried into his bedroom at Putney, the Marquess Wellesley, whom he had long loved, whom he had sent to govern India, and whose administration had been eminently able, energetic and successful, arrived in London after an absence of eight years. The friends saw each other once more. There was an affectionate meeting and a last parting. That it was a last parting Pitt did not seem to be aware. He fancied himself to be recovering, talked on various subjects cheerfully and with an unclouded mind, and pronounced a warm and discerning eulogium on the marquis's brother Arthur. "I never," he said, "met with any military man with whom it was so satisfactory to converse." The excitement and exertion of this interview were too much for the sick man. He fainted away; and Lord Wellesley left the house convinced that the close was fast approaching.

And now members of parliament were fast coming up to London. The chiefs of the Opposition met for the purpose of considering the course to be taken on the first day of the session. It was easy to guess what would be the language of the king's speech, and of the address which would be moved in reply to that speech. An amendment condemning the policy of the government had been prepared, and was to have been proposed in the House of Commons by Lord Henry Petty (afterwards 3rd marquess of Lansdowne). He was unwilling, however, to come forward as the accuser of one who was incapable of defending himself. Lord Grenville, who had been informed of Pitt's state by Lord Wellesley, and had been deeply affected by it, earnestly recommended forbearance; and Fox, with characteristic generosity and good nature, gave his voice against attacking his now helpless rival. "I am the very last," he said, "et mentem mortalia tangunt." On the morning of the 23rd of January 1806, the twenty-fifth anniversary of the day on which he first took his seat in parliament, it was moved in the House of Commons that Pitt should be honoured with a public funeral and a monument. The motion was opposed by Fox in a speech which deserves to be studied as a model of good taste and good feeling. The task was the most invidious that ever an orator undertook; but it was performed with a humanity and delicacy which were warmly acknowledged by the mourning friends of him who was gone. The motion was carried by 288 votes to 89. The 22nd of February was fixed for the funeral. The corpse, having lain in state during two days in the Painted Chamber, was borne with great pomp to the northern transept of the Abbey. A splendid train of princes, nobles, bishops and privy councillors followed. The grave of Pitt had been made near to the spot where his great father lay, near also to the spot where his great rival was soon to lie. Wilberforce, who carried the banner before the hearse, described the awful ceremony with deep feeling. As the coffin descended into the earth, he said, the eagle face of Chatham from above seemed to look down with consternation into the dark house which was receiving all that remained of so much power and glory.

Pitt was emphatically the man of parliamentary government, the type of his class, the minion, the child, the spoiled child, of the House of Commons. He was a distinguished member of the House of Commons at twenty-five. The ability which he had displayed in the House of Commons made him the most powerful subject in Europe before he was twenty-five. It was when the House of Commons was to be convinced and persuaded that he put forth all his powers. Of those powers we must form our estimate chiefly from tradition; for, of all the eminent speakers of that age, Pitt has suffered most from the reporters. Even while he was still living, critics remarked that his eloquence could not be preserved, that he must be heard to be appreciated. They more than once applied to him the sentence in which Tacitus describes the fate of a senator whose rhetoric was admired in the Augustan age: "Hateri canorum illud et profundi cum ipsa simile extinxtum est." There is, however, abundant evidence that nature had bestowed on Pitt the talents of a great orator; and those talents had been developed in a very peculiar manner, first by his education, and secondly by the high official position to which he rose early, and in which he passed the greater part of his public life.

At his first appearance in parliament he showed himself superior to all his contemporaries in command of language. He could pour forth a long succession of round and stately periods, without premeditation, without ever pausing for a word, without ever repeating a word, in a voice of silver clearness, and with a pronunciation so articulate that not a letter was slurred. He had less amplitude of mind and less richness of imagination than Burke, less ingenuity than Windham, less wit than Sheridan, less perfect mastery of dialectical fence and less of that highest sort of eloquence which consists of reason and passion fused together than Fox. Yet the most unanimous judgment of those who were in the habit of listening to that remarkable race of men placed Pitt, as a speaker, above Burke, above Windham, above Sheridan and not below Fox. His declamation was copious, polished and splendid. In power of sarcasm he was probably not surpassed by any speaker, ancient or modern; and of this formidable weapon he made merciless use. In two parts of the oratorical art which are of the highest value to a minister of state he was singularly expert. No man knew better how to be luminous or how to be obscure. When he wished to be understood, he never failed to make himself understood. Nothing was out of place; nothing was forgotten; minute details, dates, sums of money, were all faithfully preserved in his memory. On the other hand, when he did not wish to be explicit—and no man who is at the head of affairs always wishes to be explicit—he had a marvellous power
of saying nothing in language which left on his audience the impression that he had said a great deal.

The effect of oratory will always, to a great extent depend on the character of the orator. There perhaps never were two speakers whose eloquence had more of what may be called the race, more of the flavour imparted by moral qualities, than Fox and Pitt. The speeches of Fox owe a great part of their charm to that warmth and softness of heart, that sympathy with human suffering, that admiration for everything great and beautiful, and that hatred of cruelty and injustice, which interest and delight us even in the most defective reports. No person, on the other hand, could hear Pitt without perceiving him to be a man of high, intrepid and commanding spirit, proudly conscious of his birth and position, of his superiority, incapable of the low vices of fear and envy, but too prone to feel and to show disdain. Pride, indeed, pervaded the whole man, was written in the harsh, rigid lines of his face, was marked by the way in which he walked, in which he sat, in which he stood, and above all, in which he bowed. Such pride, of course, inflicted many wounds. But his pride, though it made him bitterly disliked by individuals, inspired the great body of his followers in parliament and throughout the country with respect and confidence. It was that of the magnanimous man so finely described by Aristotle in the Ethics, of the man who thinks himself worthy of great things, being in truth worthy. It was closely connected, too, with an ambition which had no mixture of low coidpity. There was something noble in the cynical disdain with which the mighty minister scattered riches and titles to right and left among those who valued them, while he spurned them out of his way. Poor himself, he was surrounded by friends on whom he had bestowed three thousand, six thousand, ten thousand a year. Plain Mister himself, he had made more lords than any three ministers that had preceded him. The garter, for which the first dukes in the kingdom were contending, was repeatedly offered to him, and offered in vain.

The correctness of his private life added much to the dignity of his public character. In the relations of son, brother, uncle, master, friend, his conduct was exemplary. In the small circle of his intimate associates he was amiable, affectionate, even playful. He indulged, indeed, somewhat too freely in wine, which he had early been directed to take as a medicine, and which use had made a necessary of life to him. But it was very seldom that any indication of undue excess could be detected in his tones or gestures; and, in truth, two bottles of port were little more to him than two dishes of tea. He had, when he was first introduced into the clubs of St James' Street, shown a strong sense for play; but he had the prudence and the resolution to stop before this taste had acquired the strength of habit. From the passion which generally exercises the most tyrannical dominion over the young he possessed an immunity, which is probably to be ascribed partly to his temperament and partly to his situation. His constitution was feeble; he was very shy; and he was very busy. The strictness of his morals furnished such buffoons as Peter Pindar and Captain Morris with an inexhaustible theme for merriment of no very delicate kind. But the great body of the middle class of Englishmen could not see the joke. They warmly praised the young statesman for commanding his passions, and for covering his frailties, if he had frailties, with decorous obscurity.

The memory of Pitt has been asstilled, times innumerable, often justly, often unjustly; but it has suffered much less from his assailants than from his eulogists. For, during many years, his name was the rallying cry of a class of men with whom, at one of those terrible conjunctures which confound all ordinary distinctions, he was accidentally and temporally connected, but to whom, on almost all great questions of principle, he was diametrically opposed. The haters of parliamentary reform called themselves Pittites, not choosing to remember that Pitt made three motions for parliamentary reform, and that, though he thought that such a reform could not safely be made while the passions excited by the French Revolution were raging, he never uttered a word indicating that he should not be prepared at a more convenient season to bring the question forward a fourth time. The toast of Protestant ascendency was drunk on Pitt's birthday by a set of Pittites who could not but be aware that Pitt had resigned his office because he could not carry Catholic emancipation. The defenders of the Test Act called themselves Pittites, though they could not be ignorant that Pitt had laid before George III. unanswerable reasons for abolishing the Test Act. The enemies of free trade called themselves Pittites, though Pitt was far more deeply imbued with the doctrines of Adam Smith than either Fox or Grey. The very negro-drivers invoked the name of Pitt, whose eloquence was never more conspicuously displayed than when he spoke of the wrongs of the negro. This mythical Pitt, who resembles the genuine Pitt as little as the Charlemagne of Ariosto resembles the Charlemagne of Eginehard, has had his day. History will vindicate the real man from calumny disguised under the semblance of adulation, and will exhibit him as what he was—a minister of great talents, honest intentions and liberal opinions, pre-emminently qualified, intellectually and morally, for the part of a parliamentary leader, and capable of administering with prudence and moderation the government of a prosperous and tranquil country, but unequal to surprising and terrible emergencies, and liable in such emergencies to err grievously, both on the side of weakness and on the side of violence.

AUTHORITIES.—Lord Macaulay's article, a classic on its subject, written in 1839 for this Encyclopedia and included in the 9th edition unabridged, is preserved above in its essentials, but has been shortened and readjusted. Among standard biographies are the 5th Earl Stanhope's important Life (4 vols., 2nd ed., 1862), and Lord Rosebery's masterly study in the Twelve English Statesmen Series (1891). See also the bibliographical note to the Rev. William Hinri's article on Pitt in the Dict. Nat. Biog., and also the same historian's app. i., pp. 461-462, to his vol. x. (for the years 1760-1801) of The Political History of England (1905), dealing with the authorities for the period.

PITTA, in ornithology, from the Telugu pitta, meaning a small bird, translated by Vieillot in 1816 (Analyse, p. 42) as the name of a genus, and since adopted by English ornithologists as the general name for a group of birds, called by the French Brèves, and remarkable for their great beauty.¹ For a long while the

¹ In ornithology the word is first found as part of the native name, "Pomniky pitta," of a bird, given in 1713 by Petch in the "Manuel," to Ray's Synt. (p. 158), on the authority of Buckley (see Ornithology). This bird is the Pitta bengalensis of modern ornithologists, and is said by Jerdon (Birds of India, i. 503) now to bear the Telugu name of Pana-inki.

Pitta elegans, male and female.
family was gradually admitted. Their position was partly determined by A. H. Garrod, who, having obtained examples for dissection, in a communication to the Zoological Society of London, advanced in its proceedings for 1876, proved (pp. 512, 513), that the Pittidae belonged to that section of Passerine birds which he named Mesomyodi, since their syrinx, like that of the Tyrannidae (see KING-BIRDS), has its muscles attached to the middle of its half-rings, instead of to their extremities as in the higher Passerines or Acromyodi. They are now placed as a separate family Pittidae of the Clamatores division of the Anisomyodi Passeres. There are about fifty species, divided into a number of genera, confined to the Old World, and ranging from India and North China to Australia, New Guinea and New Britain, with one species in West Africa, the greatest number being found in Borneo and Sumatra. Few birds can vie with the Pittas in brightly-contrasted coloration. Deep velvety black, pure white and intensively vivid scarlet, turquoise-blue and beryl-green—and occupying a considerable extent of surface—are found in a great many of the species—to say nothing of other composite or intermediate hues; and, though in some a modification of these tints is observable, there is scarcely a trace of any blending of shade, each patch of colour standing out distinctly. This is perhaps the more remarkable as the feathers have hardly any lustre to heighten the effect produced, and in some species the brightest colours are exhibited by the plumage of the lower parts of the body. Pittas vary in size from that of a jay to that of a lark, and generally have a bill which is little longer than the head, and the legs, which is often high with scutellated "tarsi," and a very short tail. In many of the forms there is little or no external difference between the sexes.

Placed originally among the Pittidae, but now created to form an allied family Philepittidae, is the genus Philepis, consisting of two species peculiar to Madagascar. The two species which compose it have little outward resemblance to the Pittas, not having the same style of coloration and being apparently of more arboreal habits. The sexes differ greatly in plumage, and the males have the skin round the eyes bare of feathers and carunculated.

Pittacus, of Mytilene in Lesbos (c. 650–570 B.C.), one of the Seven Sages of Greece. About 611, with the assistance of the brothers of the poet Alcaeus, he overthrew Melanchrus, tyrant of Lesbos. In a war (606) between the Mytileneans and Athenians for the possession of Sigum on the Hellespont he slew the Athenian commander Phrynon in single combat. In 589 his fellow citizens entrusted Pittacus with despotic power (with the title of Assymetes) for the purpose of protecting them against the exiled nobles, at the head of whom were Alcaeus and his brother Antimenides. He resigned the government after holding it for ten years, and died ten years later. According to Diogenes Laërtius, who credits him with an undeniably spurious letter to Croesus (with whom his connexion was probably legendary), Pittacus was a writer of elegiac poems, from which he quotes five lines. His favourite sayings were: "It is hard to be good," and "Know when to act."

See Herodotus v. 37, 94: Diog. Laërt. i. 4: Lucian, Macrobii, 18: Strabo xiii. 609, 617–618; Aristotle, Politik, ii. 12, iii. 14: T. Benèc, Poëtae lyrici graeci.

PITTANCE (through O. Fr. piéance, from Lat. pietas, loving-kindness), properly a gift to the members of a religious house for masses, consisting usually of an extra allowance of food or wine on occasions such as the anniversary of the donor's death, festivals and the like. The word was early transferred to a charitable donation and to any small gift of food or money.

PITT-RIVERS, AUGUSTUS HENRY LANE-FOX (1827–1900), English soldier and archaeologist, son of W. A. Lane-Fox, was born on 9 April 1827, and he assumed the name of Pitt-Rivers, on inheriting the Dorset and Wiltshire estates of his great-uncle, the second Lord Rivers. Educated at Sandhurst, he received a commission in the Grenadier Guards in 1845, being captain 1850, lieutenant-colonel 1857, colonel 1867, major-general 1877 and lieutenant-general 1882. He served in the Crimean War, and was at the Alma and the siege of Sebastopol. His talent for experimental research was utilized in investigation into improvements of the army rifle, and he was largely responsible for starting the Hythe School of Musketry. It is not, however, in his military career, but in his work as an anthropologist and archaeologist, that General Pitt-Rivers will be remembered. His interest in the evolution of the rifle early extended itself to other weapons and instruments in the history of man, and he became a collector of articles illustrating the development of human invention. His collection became famous, and, after being exhibited in 1874–1875 at the Bethnal Green Museum, was presented in 1883 to the university of Oxford. When, in 1886, General Pitt-Rivers obtained possession of his great-uncle's estates—practically untouched by the excavator since they had been the battleground of the West Saxons, the Romans and the Britons—he devoted himself to the curation of the collections round Rushmore resulting from great valuable "finds"; he founded a local museum and published several illustrated volumes. As a scientific archaeologist he attained high rank. Oxford gave him the D.C.L. in 1886; he was president of the Anthropological Institute, and F.R.S. He married, in 1853, Alice Margaret, daughter of the second Lord Stanley of Alderley, and had a numerous family; his second daughter became in 1884 the wife of Sir John Lubbock (Lord Avebury). General Pitt-Rivers died at Rushmore on the 4th of May 1900.

PITTSBURG, a city of Crawford county, Kansas, U.S.A., about 130 m. S. of Kansas City. Pop. (1880), 6241; (1880), 6677; (1900) 10,072, of whom 506 were foreign-born; (1910) census, 14,755. It is situated at the intersection of four great railway systems—the Atchison Topeka & Santa Fe, the St. Louis & San Francisco, the Kansas City Southern (which maintains shops here), and the Missouri Pacific, and is served by inter-urban electric railways. The city is the seat of the State Manual Training Normal School (1903) and of the Pittsburg Business College. Pittsburg is situated near the lead and zinc region of south-east Kansas and south-west Missouri, is in the midst of a large and rich bituminous coalfield, and lies near natural gas and oil fields. Among the manufactures are zinc spelter—there are large smelters here—clay products (chiefly vitrified brick, sewer pipe and tile; the clay being obtained from a great underlying bed of shale), blending powder, packing-house products and planing-mill products. The total value of the city's factory products in 1905 was $1,824,929. Pittsburg was settled about 1879, was chartered as a city in 1886, and became a city of the first class in 1908.

PITTSBURG, or PITTSBURGH, the second largest city of Pennsylvania, U.S.A., and the county-seat of Allegheny county, on the Allegheny, Monongahela and Ohio rivers, 440 m. by rail W. by S. of New York City, 306 m. W. by N. of Philadelphia, 365 m. N.W. of Washington and 468 m. E. by S. of Chicago. Pop. (1890), 358,617; (1900), 431,616, of whom 84,578 were foreign-born, 17,740 were negroes and 154 were Chinese; (1910 census, after the annexation of Allegheny), 593,925. Of the 84,578 foreign-born in 1900, 21,222 were natives of Germany, 15,620 of Ireland, 8902 of England, 6243 of Russian Poland, 3709 of Italy, 4107 of Russia, 3515 of Austria, 3515 of German Poland, 2559 of Wales, 2264 of Scotland, 2124 of Hungary, 1072 of Sweden and 1023 of Austrian Poland. Area (including Allegheny, annexed in 1866), 40-47 sq. m. Pittsburg is served by the Pennsylvania (several divisions), the Baltimore & Ohio, the Pittsburg & Lake Erie (controlled by the New York Central System), the Pittsburg, Cincinnati, Chicago & St Louis (controlled by the Pennsylvania Company), the Pittsburg, Chartiers & Youghiogheny (controlled jointly by the two preceding railways; m. of track), the Buffalo, Rochester & Pittsburg, and the Wheeling & Pittsburg Terminal m. to Pittsburgh Junction, Ohio; controlled by the Wabash railway, and the Pittsburg Terminal (also controlled by the Wabash and operating the
West Side Belt, from Pittsburgh to Clairton, 21 m,) railways, and by river boats on the Ohio, Monongahela and Allegheny.

Pictesque rolling plateaus, the three rivers and narrow valleys, from which rise high hills or precipitous bluffs, are the principal natural features of the district, to which the city extends. Retail houses, wholesale houses, banks, tall office buildings, hotels, theatres and railway terminals are crowded into the angle, or “The Point,” formed at the confluence of the Allegheny and Monongahela rivers, with Fifth Avenue as the principal thoroughfare, especially for the retail houses, and Fourth Avenue as the great banking thoroughfare. Factories extend for miles along the banks of all three rivers into the tributary valleys, and are the cause of Pittsburgh’s nickname, “The Smoky City. The more attractive residential districts are on the plateau in the eastern portion of the district between the Allegheny and Monongahela rivers and on the hills overlooking the Allegheny river from the north. Overlooking the Monongahela river is Schenley Park (about 422 acres), the first city park, of which about 400 acres were given to the city in 1890 by Mrs. Mary E. Schenley. About 2. m. to the north, overlooking the Allegheny river, is Highland Park (about 366 acres), which contains the city reservoirs and a picturesque lake. Adjacent to Schenley Park are Homewood and Calvary cemeteries; and adjacent to Highland Park is Allegheny Cemetery. Across the Allegheny river, in the Allegheny district, are the beautiful Riverview Park (240 acres), in which is the Allegheny Observatory, and West Park (about 100 acres). A number of bridges span these waters.

The city has some fine public buildings, office buildings and churches. The Allegheny county court-house (1884–1888) is one of H. H. Richardson's masterpieces. The Nixon theatre is also notably architecturally. The high Frick Office building has exterior walls of white granite; in its main hall is a stained-glass window by John La Farge representing Fortune and her wheel. A large government building of polished granite contains the post office and the customs offices. St. Paul's Cathedral (Roman Catholic, 1903–1906) is largely of Indiana limestone.

The city is the see of a Roman Catholic and a Protestant Episcopal bishop. In Schenley Park is the Carnegie Institute (established by a gift of $70,000,000 from Andrew Carnegie), who made further contributions of $9,000,000 for its maintenance), with a main building containing a library, a department of fine arts, a museum (see MUSEUMS OF SCIENCE) and a music hall, and several separate buildings for the technical schools, which had 2102 students in 1909. The main building, dedicated in April 1907, is 660 ft. long and 400 ft. wide; in its great entrance hall is a series of mural decorations by John White Alexander, a native of the city. The library, in which the institution had its beginning in 1895, contains about 306,000 volumes. The Phipps Conservatory was presented to the city in 1893 by Henry Phipps (b. 1839), a steel manufacturer associated with Andrew Carnegie. It is the largest in America, and, with its Hall of Botany, which is utilized in instructing school children in botany, is situated in Schenley Park. The conservatory is maintained by municipal appropriations. There is a zoological garden in Highland Park. In December 1907 it was decided that the several departments of the Western University of Pennsylvania, then in different parts of the city, should be brought together on a new campus of 43 acres near the Carnegie Institute. In July 1908 the name was changed to “The University of Pittsburgh.” The university embraces a college and engineering school, the Western Pennsylvania School of Mines and Mining Engineering, a graduate department, an evening school of economics, accounts and finances, a summer school, evening classes, summer classes, factories, chemical and department are aluminum, and Allegheny Observatory, in the Allegheny district), law (the Pittsburgh Law School), medicine (the Western Pennsylvania Medical College), pharmacy (the Pittsburgh College of Pharmacy) and dentistry (the Pittsburgh Dental College). The institution had its beginning in the Pittsburgh Academy, which was opened about 1770 and was incorporated in 1787. It was incorporated as the Western University of Pennsylvania in 1819, but was only a college from that date until 1892, when the Western Pennsylvania Medical College became its department of medicine. In 1895 the department of law was added, the Pittsburgh College of Pharmacy was united to the university, and the college was opened for the first time admitted. In 1896 the department of dentistry was established. The college had 151 instructors and 1243 students. In the east end is the Pennsylvania College for Women (Presbyterian; chartered in 1869), with preparatory, collegiate and musical departments. In the Allegheny district are the Allegheny Theological Seminary (United Presbyterian, 1823), the Western Theological Seminary (Presbyterian, opened 1827), and the Reformed Presbyterian Theological Seminary (1836). Although Allegheny is now a part of Pittsburgh, the two public school systems remain independent. The Pittsburgh High School (five buildings in 1910) has a normal course; and there are various private schools and academies.

The Pittsburgh Gazette-Times is probably the oldest newspaper west of the Allegheny Mountains; the Gazette was founded in 1786 and in 1906 was consolidated with the Times (1879). Other prominent newspapers of the city are the Dispatch (1846), the Chronicle Telegraph (1841), the Post (1792; daily, 1842), which is one of the few influential Democratic newspapers in Pennsylvania, the Leader (Sunday, 1864; daily, 1870) and the Press (1883). Two German dailies, one Slavonic daily, one Slavonic weekly, two Italian weeklies, and iron, building, coal and glass trade journals are published in the city. In Pittsburgh is the publishing house of the United Presbyterian Church, and The Christian Advocate (weekly, Methodist Episcopal, 1834) is published here under the auspices of the general conference.

The oldest hospital is the Reineeman (private; 1803) for maternity cases; the municipal hospital (1878) for contagious diseases; the Sisters of Charity, the Sisters of Mercy, the Institution of Protestant Deaconesses, the Presbyterian Church and the United Presbyterian Woman's Association each have charge of a hospital; and there is also an eye, ear and throat hospital (1895). The Western Pennsylvania Institution for the instruction of the deaf and dumb (1876), in Edgewood Park, is in part maintained by the state. And the state assists the Home for Aged and Infirm Colored Women (1881), and the Home for Colored Children (1881). Among other charitable institutions are the Curtis Home (1894) for destitute women and girls, the Bethesda Home (1890) for homeless girls and their children, the Florence Crittenton Home (1893) for homeless and unfortunate women, the Roselia Foundling Asylum and Maternity Hospital (1891), the Protestant Home for Incurables (1883), the Pittsburgh Newsboys' Home (1894), the Children's Aid Society of Western Pennsylvania, the Pittsburgh Association for the Improvement of the Poor and the Western Pennsylvania Humane Society.

Pittsburgh is in the midst of the most productive coalfields in the country; the region is also rich in petro/um and natural gas. The city is on one of the main lines of communication between the east and the west, is the centre of a vast railway system, and has freight yards with a total capacity for more than 60,000 cars. Its harbour has a total length on the three rivers of 27.2 m., and an average width of about 1000 ft., and has been deepened by the construction (in 1877–1883) of the Davis Island dam, by dredging, under a federal project of 1899. Slack water navigation has been secured on the Allegheny by locks and dams (1890 and 1896 sq. ft.) at an expense up to July 1909 of $1,658,804; and to that time $263,625 had been spent for open-channel work. The Monongahela from Pittsburgh to the West Virginia state line (91.5 m.) was and women (1890 sq. by a private company which built seven locks and dams; this property was condemned and bought for $3,761,615 by the United States government in 1897, and, under the project of 1899 for rebuilding three of the locks and enlarging another, and that of 1907 for a new lock and dam and for other improvements, $2,675,692 was spent up to July 1909. Coal is brought to the city from the coalfields by boats on the Allegheny and Monongahela rivers as well as by rail, and
great fleets of barges carry coal and other heavy freight, such as steel rails, cotton timbers, sheet iron, wire and nails, down the Ohio in the winter and spring. A ship canal to provide water communication between Pittsburg and Lake Erie has been projected. These railways have a heavy tonnage of coal, coke and iron and steel products, and a large portion of the iron ore that is produced in the Lake Superior region is brought to Pittsburg. In 1808 the river traffic amounted to 9,090,146 tons, most of which was carried on barges down the Ohio. Pittsburg is also a port of entry; in 1907 the value of its imports amounted to $2,416,397, and in 1909 to $2,262,162.

The value of the factory products in 1905 was $165,428,881, and to this may be added $45,830,272 for those of the city of Allegheny, making a total of $211,259,153. In the manufacture of iron and steel products Pittsburg ranks first among the cities of the United States, the value of these products amounting in 1905 to $885,200,825 or 52.7% of the total for all manufactures; if the manufactures of Allegheny be added they amounted to $329,039,860 or 43.7%. Several neighboring cities and towns are also extensively engaged in the same industry, and in 1902 Allegheny county produced about 24% of the pig-iron, nearly 34% of the Bessemer steel, more than 44% of the open-hearth steel, more than 53% of the crucible steel, more than 24% of the steel rails, and more than 59% of the structural shapes that were made in that year in the United States. In 1905 the value of Pittsburg's foundry and machine shop-products was $6,631,541; of the product of steam railway repair shops, $3,726,090 (being 42.8% more than in 1900); of malts liquors, $1,206,890; of slaughtering and meat-packing products, $2,733,247; of cigars and cigarettes, $2,107,228; of glass, $2,193,540; and of tin and terne plate, $1,645,570. Electrical machinery, apparatus and supplies were manufactured largely in the city (value in 1905, $1,709,557), and there was another large plant for their manufacture immediately outside of the city limits. Coke, cut cork, rolled brass and copper were other important products in 1905. In 1900, and for a long period preceding, Pittsburg ranked first among American cities in the manufacture of glass, but in 1905 it was outranked in this industry by Muncie, Indiana, Millville, New Jersey, and Washington, Pennsylvania; but in the district outside of the city limits of Pittsburg much glass is manufactured, so that the Pittsburg glass district is the greatest in the country, and there are large glass factories at Washington (18 m. south-west), Charleroi (20 m. south) and Tarentum (15 m. north-east). In Pittsburg or the immediate vicinity are the more important plants of the United States Steel Corporation, including that of the Carnegie Company. Here, too, are the plants of the Westinghouse Company for the manufacture of electrical apparatus, of air brakes invented by George Westinghouse (born 1840), and of devices for railway signals which he also invented. In the Allegheny district the H. J. Heinz Company has its main pickle plant, the largest establishment of its kind in the country.

The Pittsburg charter of 1786 vested the more important powers of the city government in a common council of 15 members and a select council of 9 members, and until 1834 the mayor was appointed annually by these city councils from their own number. By the Wallace Act of the state legislature in 1874 a form of government was provided for cities of three classes, and Pittsburg became a city of the second class (population between 100,000 and 300,000); under the act of 1805 a new classification was made, under which Pittsburg remains in the second class. An act of 1867 had amended the provisions of the Wallace Act in regard to second class cities by changing the term for the select councilmen from two to four years and of common councilmen from two years. In 1901 a new act was passed for the government of cities of the second class. It provided that the executive be a "city recorder"; this provision was repealed in 1903, when the title of mayor again came into use. The mayor holds office for three years, has the powers and jurisdiction of a justice of the peace, appoints the heads of departments (public safety, public works, collector of delinquent taxes, assessors, city treasurer, law, charities and correction, and sinking fund commission), and may remove any of the officers he has appointed, by a written order, showing cause, to the select council. The city controller is elected by popular vote. The legislative bodies are the select and common council, elected under the law of 1887; by a three-fifths vote it may pass resolutions or ordinances over the mayor's veto. The department of public safety controls the bureaus of police, detectives, fire, health, electricity and building inspection; the department of public works controls bureaus of surveys, construction, highways and sewers, city property, water, assessment of water, rents, parks, deed registry, bridges and light. In 1909 the taxable valuation was $100,771,321, and the tax rate was 13.8 mills for city property, 9.2 mills on rural property and 6.9 mills on agricultural property. The tax rate for separate indebtedness varied from 6 mills in Allegheny to 16.2 mills in the 36th ward. The_apply within the Allegheny river and pumped into reservoirs, the highest of which, in Highland Park, is 367 ft. above the river; and there is a slow sand filtration plant for the filtration of the entire supply.

Pittsburg owed its origin to the strategic value of its site in the struggle between the English and the French for the possession of the North American continent. A few Frenchmen attempted to establish a settlement here in 1731, but were soon driven away by the Indians. In 1753, after the French had laid formal claim to this region and the Ohio Land Company had been formed with a view to establishing a settlement within it, the town of Pittsburgh was laid out by the Dichwile, general of Virginia and a shareholder in the Ohio Company. George Washington was appointed "the commandant of the French forces on the Ohio" (then stationed at Fort Le Boeuf, near the present Waterford, about 115 m. north of the head-waters of that river) asking him to account for his invasion of territory claimed by the English. This was Washington's first important public service. He reached the present site of Pittsburg on the 24th of November 1753, and subsequently reported1 that what is now called "The Point," i.e. the tongue of land formed by the confluence of the Monongahela and Allegheny rivers, was a much more favourable situation for a fort and trading post than the one about two miles up the Monongahela (near the present site of McKees Rocks) which had been tentatively selected by the Ohio Company. Accordingly, on the 17th of February 1754, a detachment of about 40 soldiers, under the command of Captain William Trent, reached "The Point," and began to build a fortification (under the auspices of the Ohio Company), which it seems to have been the intention to call Fort Trent, and which was the beginning of the permanent settlement here by whites. On the 17th of the following April, however, Ensign Edward Ward, commanding the soldiers, in the absence of Captain Trent, was forced to evacuate the unfinished fortification by a party of about 1000 French and Indians, under Captain Contrecoeur, who immediately occupied the works, which he enlarged and completed, and named Fort Duquesne, in honour of Duquesne de Menneville, governor of New France in 1729-1755. In the following summer Washington attempted to recover this fort, in a campaign which included the skirmish

1 His Journal, published in 1754, gives a concise and lucid account of this expedition.

2 William Trent (c. 1715-1778) was a native of Lancaster county, Pennsylvania, became a captain in the state militia in 1746 and served against the French and Indians, was for many years, after 1749, a justice of the peace of common pleas and general sessions of the peace for Cumberland county, Pennsylvania, and in 1750-1756 was the partner of George Croghan in an extensive trade with the Indians. According to one account, he visited the site of Pittsburg before its formation, in the winter of 1753-1754, and devoted its site for fortification. On August 7, 1754, before the arrival of Washington. In 1755 he became a member of the council of Lieut.-Governor Robert H. Morris, and in 1756 was a member of the Pennsylvania's expedition against Fort Duquesne. He acted many times as Indian agent; his lucrative trade with the Indians, conducted from a trading house near Fort Pitt, was ruined during Pontiac's conspiracy. At the beginning of the War of Independence he was given a major's commission to raise troops in Western Pennsylvania. See Journal of Captain William Trent (Cincinnati, Ohio, 1871), edited by Alfred T. Goodman.
PITTSBURG

681

(considered—Seven Years—War) on the 28th of May 1754, at Great Meadows (in what is now Wharton township, Fayette county, Pennsylvania, about 50 m. south-east of Pittsburg). In command under his command and a scouting party under N. Coulon de Jumonville, in which Jumonville and several of his men were killed; the building, at Great Meadows, by Washington, of Fort Necessity, and its capitulation (July 3); and the retreat of Washington to Virginia. Another expedition, led by Major-General Edward Braddock, resulted in the engagement known as "Braddock's Defeat" (July 9, 1755), fought within the present borough of Braddock (about 8 m. east of Fort Duquesnes), in which Braddock's force was practically annihilated, and Braddock was mortally wounded, dying four days later. The fort was finally recaptured by the English in 1758, as the result of an elaborate expedition (involving about 7000 troops) planned by Brigadier-General John Forbes (1710-1759), and prosecuted, with the assistance of Colonel George Washington and Colonel Henry Bouquet, in the face of great difficulties. General Forbes himself was so ill that he had to be carried in a litter throughout the campaign. The troops having rendezvoused during the summer (of 1758) at Ray's Town (now Bedford, Pennsylvania), and at Loyalhanna creek (now in Westmoreland county), about 50 m. to the north-west (where Fort Ligonier was built), Colonel Bouquet, commanding the division at the latter place, despatched Major James Grant (1720-1780) at the head of about 800 men to reconnoitre the fort. Grant advanced to a hill (still known by his name, and upon the crest of which the court-house now stands) within about a quarter of a mile of the fort. Here he rashly divided his force, and in a sortie of French and Indians, on the morning of the 14th of September, one of his divisions was surrounded, and a general rout ensued in which about 270 of Grant's men were killed, about 40 were wounded, and others (including Grant) were taken prisoners. Forbes's army advanced to within about 15 m. of the fort on the 24th of November, whereupon the French blew up part of the works, set fire to the buildings and retreated down the Ohio in boats. The English occupied the place on the next day and General Forbes ordered the immediate erection of a stockade fort near the site of the old one. In reporting to Lieut.-Governor William Denny (Nov. 26) the success of the expedition he dated his letter from Fort Duquesne "or now Pitts-Bourgh," and this name, with its subsequent modification "Pittsburgh," was thereafter more commonly used than that of Fort Pitt, which, as designating the fortification proper appears to have been first applied by General John Stanwix to the enlarged fort built (at a cost, it was estimated, of $60,000) chiefly under his direction during 1759-1760.

The first considerable settlement around the fort sprang up in 1760; it was composed of two groups of houses and cabins, the "lower town," near the fort's ramparts; and the "upper town," built chiefly along the banks of the Monongahela, and extending as far as the present Market Street. In April 1761, according to a census of the settlement, outside of the fort, taken for Colonel Bouquet, there were 332 inhabitants and 193 houses.

Fort Pitt was one of the important objective points of Pontiac's conspiracy (1763), and as soon as the intentions of the Indians became evident, Captain Simeon Ecuyer, the Swiss officer in command of the garrison (which then numbered about 350), had the houses outside the ramparts levelled and prepared for a siege. The Indians attacked the fort on the 22nd of June (1763), and kept up a continuous, though ineffective, fire upon it from the 27th of July until the 1st of August, when they drew off and advanced to meet the relieving party, which, however, was defeated by Forbes, Bouquet and Run, and Colonel Bouquet relieved the fort on the 10th of August (see PONTIAC). In 1764 Colonel Bouquet added to the fort a redoubt, the "Block House," which still stands, the sole remaining trace of Fort Pitt, and is owned and cared for by the Daughters of the American Revolution.

A second town, laid out in 1764, by Colonel John Campbell (with the permission of the commandant at Fort Pitt), is bounded in the present city by Water Street, Market Street, Second Avenue and Ferry Street, and comprises four blocks. In November 1768, at a general council of the Six Nations with Sir William Johnson, the British representatives of Pennsylvania and Virginia, held at Fort Stanwix, on the site of the present city of Utica, New York (q.v.), at which was signed a treaty establishing the boundary line between the English possessions and the territory claimed by the Six Nations, the Indians sold for $10,000 to Thomas Penn (1702-1775) and Richard Penn (1706-1771), respectively, the second and third sons of William Penn—the founder of Pennsylvania—by his second wife, the remaining land in the province of Pennsylvania to which they claimed title, namely the tract lying south of the west branch of the Susquehanna river and of a straight line from the north-west corner of what is now Cambria county to the present Kittanning (in Armstrong county), and all of the territory east of the Allegheny river below Kittanning and south of the Ohio river. To this transaction the commissioner from Virginia seems to have made no objection, though the tract included the Fort Pitt region and other territory then claimed by Virginia. In January-March 1769 the Penns caused to be surveyed the "Manor of Pittsburgh," a tract of about 5500 acres, including much of the original city, intending to reserve it for their private use; but in the following April they offered at public sale the lands in the remainder of their purchase of the preceding year. At this time the settlement about Fort Pitt consisted of about twenty houses, occupied chiefly by Indian traders. By order of General Thomas Gage the fort was abandoned as a military post in October 1772, and was partly dismantled. In January 1774 it was occupied by an armed force under Dr. John Connolly, a partisan of Lord Dunmore, governor of Virginia, and by him was named Fort Dunmore (which name, however, was never formally recognized), this being one of Dunmore's overt acts ostensibly in support of his contention that the Fort Pitt region was included in Augusta county, Virginia. In the following April Connolly took forcible possession of the court-house at Hanan's Town (near the present Greensburg), the county-seat of Westmoreland county (which then included the Fort Pitt region), a few days afterwards arrested the three justices who lived in Pittsburg, and for the remainder of the year terrorized the settlement. Lord Dunmore himself issued a proclamation dated "Fort Dunmore," 17th September (1774), in which he called upon the inhabitants to ignore the authority of Pennsylvania, and to recognize only that of Virginia. A year afterwards Fort Pitt was occupied by a company of Virginia soldiers by order of the Virginia Provincial Convention (assembled at Williamsburgh in August 1775), but this move apparently was more for the defence of the frontier in the coming war than an expression on the Pennsylvania-Virginia boundary dispute; and, in November, Connolly was arrested at Fredericksburg, Maryland, on the charge of furthering Dunmore's plans for invading the western frontier. The boundary itself was in controversy until 1780, and the marking of the boundary lines was not completed until 1785. During the War of Independence the fort was maintained as a frontier Indian post, and as a protection against the British at Detroit. Soon after the close of the war it was neglected, and by 1791 it was in bad repair; therefore at the time of the Indian hostilities of 1792 another stockade fort was built near the bank of the Allegheny river and about a quarter of a mile above the site of Fort Pitt, this new fort being named Fort Lafayette, or, as it was more commonly called, Fort Fayette. After General Anthony Wayne's defeat of the Indians, at Fallen Timbers, Ohio (Aug. 20, 1794), Pittsburg lost its importance as a frontier post.

The county, first organized in 1784, included all of the land included in the "Manor of Pittsburgh," was begun by the grands of William Penn, John Penn (1720-1795), the second son of Richard Penn and lieutenant-governor of Pennsylvania in 1765-1771 and in 1773-1776; and John Penn (1760-1834), the fourth son of Thomas Penn; and in the following June a new series of town lots was laid out in which was incorporated Colonel Campbell's survey. Thereafter, settlers, chiefly Scotch and Irish, came rapidly. 1 This tract was confiscated by Pennsylvania in 1779.
PITTSFIELD-GREATER PITTSFIELD. 

Pittsfield and its vicinity witnessed much of the disorder, and some of the violence against person and property, incident to the Whisky Insurrection of 1791-94. Delegates from Allegheny, Westmoreland, Washington and Fayette counties met here on the 7th of September 1791, and passed resolutions severely denouncing the excise tax; and a similar meeting, gathering, on the 24th of August 1792, voted to proscribe all persons who assisted in the enforcement of laws taxing the manufacture of liquor. Thereafter various persons who had paid the excise tax, or had assisted in collecting it, were tarred and feathered or had their houses or barns burned. General John Neville (1731-1803), having accepted the office of chief excise inspector for Western Pennsylvania, his fine country residence, about 7 m. south-west of Pittsburg, was attacked by a mob of about 500 men on the 16th and 17th of July 1794. The defenders of the property (who included a squad of soldiers from the garrison at Pittsburg) killed two and wounded several of the attacking party, but they were finally forced to surrender, and General Neville's mansion and other buildings were burned to the ground. A mass meeting of about 5000 citizens of the above-mentioned counties (many of them armed militiamen), at Braddock's Field, on the 1st and 2nd of August 1794, threatened to take possession of Fort Lafayette and to burn Pittsburg, but cooler counsel prevailed, and after voting to proscribe several persons, and marching in a body through the streets of the town, the crowd dispersed without doing any damage. Upon the arrival in the following November of the troops sent by President Washington, a military court of inquiry, held at Pittsburg, caused the arrest of several persons, who were sent to Philadelphia for trial, where some of them were found guilty and sentenced to terms of imprisonment, but the sentences were not enforced.

The town was made the county-seat in 1791, it was incorporated as a borough in 1796, the charter was revived in 1804, and the borough was chartered as a city in 1816. As early as the year of its incorporation as a borough Philadelphia and Baltimore merchants had established an important trade with it. Their goods were carried in Conestoga wagons to Shippensburg and Chambersburg, Pennsylvania, and Hagerstown, Maryland, taken from there to Pittsburgh on pack horses, and exchanged for Pittsburgh products; these products were carried by boat to New Orleans, where they were exchanged for sugar, molasses, &c., and these were carried through the gulf and along the coast to Baltimore and Philadelphia. Boat-building was begun in Pittsburg in 1797 or earlier; the galley "President Adams," built by the government, was launched here in 1798, and the "Senator Ross," completed in the same year, was launched in 1799. In 1797 glassworks which were the first to use coal as a fuel in making glass were built here; later Pittsburg profited greatly by the use of its great store of natural gas in the manufacture of glass. In 1806 the manufacture of iron was well begun, and by 1823 it had become the leading industry. On the 10th of April 1845 a considerable portion of the city was swept by fire, and in July 1877, during the great railway strike of that year, a large amount of property was destroyed by a mob. The commercial importance of the city was increased by the canal from Pittsburg to Philadelphia, built by the state in 1834 at a cost of $10,000,000. The first petroleum pipe line reached Pittsburg in 1875. A movement to consolidate the cities of Pittsburg and Allegheny, together with some adjacent boroughs, was begun in 1833-1854. It failed entirely in that year but in 1867 Lawrenceville, Peebles, Collins, Liberty, Pitt and Oakland, all lying between the two rivers, were annexed to Pittsburg; in 1857 the other annex city of Schenley district (327 sq. m. of the Monongahela river; in 1866 Allegheny (p.), although a large majority of those voting on the question in that city were opposed to it, was annexed, and in November 1907 the Supreme Court of the United States declared valid the act of the state legislature under which the vote was taken.

PITTSFIELD, a city and the county-seat of Berkshire county, Massachusetts, U.S.A., in the western part of the state along the Berkshire Hills, and about 150 m. W. of Boston. Pop. (1800), 17,751; (1900), 21,756, of whom 4344 were foreign-born; (1910 census), 32,121. Area, about 41 sq. m. It is served by the New York, New Haven & Hartford and the Boston & Albany (New York Central & Hudson River) railways, and by two inter-urban electric lines. Pittsfield is a popular summer resort; it lies in a plain about 1000 ft. above sea-level, is surrounded by the picturesque Berkshire Hills, and is situated in a region of numerous lakes, one of the largest—Lake Pontoosuc—being a summer pleasure resort. On either side of the city flow the east and west branches of the Housatonic river. Standing in the public green, in the centre of the city, is the original statue (by Launt Thompson) of the "Massachusetts Color-Bearer," which has been reproduced on the battlefield of Gettysburg, Pennsylvania. The principal institutions are the House of Mercy Hospital, with which is connected the Henry W. Bliss Memorial Training School for nurses, the Berkshire Home for aged women, the Berkshire Athenaeum, containing among the public library, the Crane Art Museum and a Young Men's Christian Association. Prominent buildings are St. Joseph's Cathedral and the buildings of the Berkshire Life Insurance Company, the Agricultural National Bank and the Berkshire County Savings Bank. In the south-western part of Pittsfield, on the boundary between it and Hancock, is Shaker Village, settled about 1790 by Shakers. Pittsfield has water-power and important manufacturing industries. In 1905 its factory products were valued at $5,573,350, or 49.1% more than in 1900. Fully half of the manufactures consist of textile goods. The first settlement in what is now Pittsfield was made in 1743, but was soon abandoned on account of Indian troubles. In 1749 the settlement was revived, but the settlers did not bring their families to the frontier until 1752. The settlement was first called "Boston Plantation," or "Poontoosuck," but in 1761, when it was incorporated as a township, the name was changed to Pittsfield, in honour of the elder William Pitt. In 1801 Pittsfield was chartered as a city. It was here, in the Appleton (or Plumnett) House, known as "Elm Knoll," and built by Thomas Gold, father-in-law of Nathan Appleton, that in 1845 Henry W. Longfellow (who married Nathan Appleton's daughter) wrote his poem "The Old Clock on the Stairs." For thirty years (1842-1872) Pittsfield was the home of the Rev. W. C. Watson, the author of numerous books, of which Lectures to Children (1834); and series, 1858) and The Student's Manual (1835) were once widely read. From 1807 to 1816 Elkanah Watson (1758-1842), a prominent farmer and merchant, lived at what is now the Country Club, and while there introduced the merino sheep into Berkshire county and organized the Berkshire Agricultural Society; he is remembered for his advocacy of the building of a canal connecting the Great Lakes with the Atlantic Ocean, and as the author of Memoirs: Men and Times of the Revolution (1853), edited by his son, W. C. Watson.

SCRANTON, a city of Luzerne county, Pennsylvania, U.S.A., on the Susquehanna river just below the mouth of the Lackawanna, about 11 m. S.W. of Scranton and about 9 m. N.E. of Wilkes-Barre. Pop. (1800), 19,302; (1900), 123,556; of whom 3594 were foreign-born; (1910 census), 160,267. It is served by the Erie, the Lehigh Valley, the Delaware, Lackawanna & Western, the Central of New Jersey, the Delaware & Hudson, and the Lackawanna & Wyoming Valley railways; there is an electric railway from Pittston to Scranton, and a
bel't-line electric railway connects Pittston with Avoca, Nanticoke, Plymouth and Wilkes-Barre. Two bridges connect the city with the borough of West Pittston (pop., 1906, 68,982). Pittston is in the midst of the richest anthracite coal region of the state, and fire-clay also abounds in the vicinity. In 1905 the value of the factory products was $7,474,028 (47.8% more than in 1900). Pittston, named in honour of William Pitt, earl of Chatham, was one of the five original towns founded in the Wyoming Valley by the Susquehanna Company of Connecticut; it was first settled about 1770 and was incorporated as a borough in 1803. It was chartered as a city in 1894.

**PITRYSIAS**. (Gr. πυρία, scurf, from πῦρ, fire), a skin disease, consisting of patches of brownish colorations of various shades and shapes, mostly on the front of the body, and often attended with itching, especially after heating exercises. The pigmentation seems to radiate from the orifices of hair-follicles. The epidermis is in a scaly condition over the patch, and among the débris of the epidermic cell there may be seen minute oval spores due to a vegetable parasite, the *Microsporon furfur*. The disease is mostly one of adult age, found all over the world, and not associated in any special way with poor general health. The treatment consists of rubbing in an ointment of potassium sulphide or one of the mercurial ointments, or using sulphur-soap habitually.

**PIURA**, the northernmost, maritime department of Peru, bounded north by the Gulf of Guayaquil, N.E. by Ecuador, S. by the departments of Cañamarca and Lambayeque, and W. by the Pacific. Area, 14,849 sq. m.; pop. (1906, estimate), 154,080—both totals exclusive of the province of Tumbes, or Tumbes (area, about 19,880 sq. m.; pop., in 1906, about 80,000), which has been administratively separated from the department for military reasons. The department belongs partly to the arid coastal plain that extends from the Gulf of Guayaquil southward nearly to Valparaiso, and partly to a broken mountainous region belonging to the Western Cordilleras. The coastal zone is traversed by the Tumbes, Chira and Piura rivers, which have their sources in the melting snows of the higher Andes and flow westward across the desert to the coast. The valleys of the Chira and Piura are irrigated and maintain large populations. Rough cotton, called "vegetable wool," and tobacco are the principal products, and are also produced in the valley of the Tumbes and in some of the elevated mountain districts. On the upland pastures cattle have long been raised, and goat-breeding has been added in modern times. Mules also are reared. Petroleum is an important product, and there are wells at a number of places along the coast, from Tumbes to Sechura, the most productive being those of Talara and Zorritos. There are sulphur deposits in the Sechura desert, and salt is manufactured at some places on the Chiribaya coast. The making of Panama hats from the fibre of the "toquilla" palm is a household industry. The capital is Piura (est. pop. 97,000 in 1906), on the Piura river, about 35 m. (direct) E.E. of Paita, and 164 ft. above sea-level. It was founded by Pizarro in 1531 under the name of San Miguel, at a place called Tangara, nearer Paita, but the present site was afterwards adopted. A railway (60 m. long) by way of Sullana connects with the port of Paita, and an extension of 6 m. runs S.S.E. to Catacos. Other towns of the department, with their estimated populations in 1906, are: Tumbes, or Tumbes (23,000), the most northern port of Peru, on the Gulf of Guayaquil, celebrated as the place where Pizarro landed in 1531; Paita; Sechura (65,500), on Sechura Bay in the southern part of the department, with exports of salt and sulphur; Sullana (30,000), an inland town with railway connexions in the fertile Chira valley; Morropon (3800) on the upper Piura; Huanacavamba, the centre of a tobacco district in the mountains; and Tambo Grande (6100) and Chulucanas (4600), both in the fertile Piura valley above the capital.

**PIUS**, the name of ten popes.

Pius I., pope from about 141 to 154. He was the brother of Hermas, author of the Shepherd.

Pius II. (Enea Silvio de' Piccolomini, known in literature as Aeneas Silvius), pope from 1458 to 1464, was born on the 18th of October 1405, at Corigliano (afterward called Pienza after him), near Siena. His family, though poor, was noble, and claimed to trace descent from Romulus. The eldest of eighteen children, he had to work on the farm with his father, until a priest taught him the rudiments of letters, which enabled him, at the age of eighteen, to go as a poor student to Siena, dividing his time between severe humanistic studies and a life of sensual pleasure. He was attracted to Florence by the teaching of Filofo. His father urged him to become a lawyer, but he accepted the position of secretary to Domenico Capranica, bishop of Fermo, and went with him to the council of Basel, where he stayed several years (1431-1435), changing masters whenever he could improve his position. As secretary of the bishop of Fermo, he was in the council of Basel, but Pope Eugenius IV.; his master was caught and imprisoned, and Aeneas only saved himself by a hasty flight. He was next (1435) employed as secretary of Cardinal Nicholas Albergati (d. 1443) at the congress of Arras, where peace was made between France and Burgundy. From here he took a long journey to Scotland and England, on a secret diplomatic mission; he had numerous adventures, in one of which he nearly lost his life. In 1436 he was back at Basel, and, although a layman, obtained a seat in the council and exercised considerable influence. In order to control it better Eugenius tried to get the council to move to Florence; a minority agreed and seceded; the majority, however, stayed where they were and took vigorous measures against the pope, culminating in his deposition on the 25th of June 1438. Aeneas took an active part in the council; and though he still declined to take orders, he was given a position on the conciliar concclave which elected Amadeus of Savoy as pope under the title of Felix V. In return for his services Felix made Aeneas papal secretary.

A new period of his career opened in 1447, when he was sent by the council to take part in the diet of Frankfort-on-Main. Here he met Frederick III. of Germany, who made him poet laureate and his private secretary. He ingratiated himself with the chancellor, Kaspar Schlick, at Vienna, one of whose adventures he celebrated in *Lucretia et Eurialus*, a novel in the style of Boccaccio. At this period he also wrote his witty but immoral play, *Chrisis*. In 1446 he took orders as subdeacon, and wrote that he meant to reform, "forsaking Venus for Bacchus," chiefly on the ground of sateity, and also, as he frankly wrote, because the clerical profession offered him more advantages than he could secure outside it.

Aeneas was useful to Frederick as a diplomatist, and managed to give all parties the impression that he was the devoted advocate of each. During the struggle between pope and council he induced Frederick to be neutral for a while. He took part in the council at Nancy and Lang (1444), and was sent on an embassy to Eugenius in the following year, he made his peace with the pope. At the diet of Frankfort (Sept. 1446) Aeneas was instrumental in changing the majority of the electors from their hostile position towards pope and emperor into a friendly one. He brought the good news to Eugenius shortly before his death (Feb. 7, 1447), and made friends with the new pope, Nicholas V., by whom he was made bishop of Siena. He was an agent of Frederick in making the celebrated concordat of Vienna (also called concordat of Aschaffenburg) in February 1448. His services to pope and emperor brought him the titles of prince of the empire and cardinal, positions which he used rather unscrupulously to get as many lucrative benefices into his hands as possible. Those in Germany brought him two thousand ducats a year.

The death of Calixtus III. (who succeeded Nicholas V.) occurred on the 5th of August 1458. After a hot fight in the conclave, in which it seemed that the wealthy French cardinal, Guillaume d'Estouteville, archbishop of Rouen and bishop of Ovita, would be elected, the intrigues of Aeneas and of his friend Rodrigo Borgia (later the notorious Alexander VI.) gave the victory to the cardinal of Siena, who took the title Pius II., with a reminiscence of Virgil's "plus Aeneas." The humanists hailed his election with joy, and flocked around to secure a share
of the good things, but they were bitterly disappointed, as Pius did not prove himself the liberal and undiscriminating patron they hoped. The fall of Constantinople in 1453 had made a deep impression upon Pius, and he never ceased to preach the crusade against the Turk. In September 1459 he opened a congress at Mantua for the purpose of considering what could be done in this direction. His proposals for the raising of troops and money met with general opposition. The French were angry because Pius had crowned the Spanish claimant, Ferdinand, king of Naples, and thus disposed of the pretensions of René of Anjou. The Germans also objected to Pius's plans, but finally agreed to furnish some troops and money, promises which they did not carry out. Pius felt how much the position of the council had fallen in importance since the days of Urban and Innocent III., and, believing that the change was due to the general councils which had asserted power over the popes, he changed his position, which before his election to the papal throne had been that of a warm advocate of the conciliar claims, and issued (Jan. 1460) the bull Exorabilis et in pristinis temporibus inauditus, in which he condemned as heretical the doctrine that the councils were superior to the popes, and proclaimed the anathema against any one who should dare to appeal to one. He issued another bull at the same time, promising forgiveness of sins to those who would take part in the crusade, and then dissolved the congress.

While Pius was at Mantua war broke out between the French and Spanish in southern Italy, and a rising of the barons devastated the Campagna. Hurrying back to Rome Pius succeeded in quelling the disorders, and sent his nephew Antonio Todeschini to the aid of Ferdinand, who made him duke of Amalfi and gave him his natural daughter Maria in marriage. This measure still further alienated the pope from the French, with whom he was at that time negotiating for the abrogation of the Pragmatic Sanction. When Louis XI. came to the throne (Nov. 1461), he sent to Pius saying that he had abolished the league of Avignon without informing the king of Naples for his own ends. When Pius refused to do anything to the prejudice of Ferdinand, Louis changed his attitude, and allowed the protests of the university of Paris and the parlements to persuade him to restore the ancient liberties of the Gallican Church. At the same time a serious quarrel with the Germans prevented anything being done towards a crusade. George Podiebrad, king of Bohemia, was plotting to depose the emperor Frederick III., who was supported by Pius. Diether, archbishop of Mainz, took the side of Podiebrad, and replied to Pius's measures by appealing to a general council. He was declared deposed by the pope, but kept his seat, and in 1464 compelled the pope to recognize him again. The quarrel with Podiebrad, who was accused of supporting the Utraquist heresy, continued with increasing bitterness, but without any decisive result, until the death of Pius. In the meantime the pope did what he could to further the cause of the crusade. The discovery of alum mines at Tolfa gave him an unexpected pecuniary resource, and to stimulate the zeal of Christendom, Pius took the cross on the 18th of June 1464. He set out for Venice, where he intended to sail for the East, but he was attacked with a fever, and on the 14th of August 1464 he died.

Pius II. was a voluminous author. Besides poems, a novel and a play, he wrote a number of orations, which were considered models of eloquence in their day. His most valuable work, however, is his Commentaries, a history of his own life and times, told in an interesting and rational manner. He is very frank about himself, and most of the adverse judgments which have been pronounced on his character have been based on his own confessions. He was an opportunist, sailing along with any favourable breeze, and not quite enough in earnest about anything to pursue the same tack steadily for long. We must give him the credit, however, of advocating a statesman-like policy in the interests of the whole of Europe in trying to get the powers to unite against the Turks, who threatened to overwhelm them all.

See Herzog-Hauck, Realencyclopie (1904), vol. xv., where a full bibliography will be found; M. Creighton, History of the Papacy during the Reformation, vol. ii. (London, 1882); L. Pastor, History of the Popes from the close of the Middle Ages (Eng. trans., 1896, vol. ii.); Voigt, Pius II. (1856-1863). The Commentaries of Pius were published in 1854, under the name of Gobelinus Persoma. His other works are found in Aeneae Sylvii opera omnia (Basel, 1851). See also Creighton, Annals of the Reformation, Annae Sibyllae (1865), vol. viii.

PIUS III. (Francesco Nanni-Todeschini-Piccolomini) was pope from the 22nd of September to the 18th of October 1534, born at Siena on the 4th of May 1459. After studying law at Perugia, he was made archbishop of Siena and cardinal-deacon of St Eustachio, when only twenty-two years of age, by his uncle Pius II., who permitted him to assume the name and arms of the Piccolomini. He was employed by subsequent popes in several important legations, as by Paul II. at the diet of Regensburg, and by Sixtus IV. to secure the restoration of ecclesiastical authority in Umbria. He bravely opposed the policy of Alexander VI., and was elected pope, amid the disturbances consequent upon the death of the latter, through the interested influence of Cardinal della Rovere, afterwards Julius II., and was crowned on the 8th of October, 1503. He permitted Cesare Borgia to return to Rome, but promptly took in hand the reform of the curia: Pius was a man of blameless life, and would doubtless have accomplished much had he lived. His successor was Julius II.

PIUS IV. (Giovanni Angelo Medici, or "Medighino", pope from 1559 to 1565, was born at Milan on the 31st of March 1499, of an obscure family, not related to the Medici of Florence (a claim to such a relationship was advanced after Giovanni Angelo had attained to prominence). The fortune of the family was established by an elder brother, Gian Giacomo, who fought his way to the highest offices and became marchese of Montefeltro and distinguished himself in the service of the emperor. Giovanni Angelo studied in Bologna and Pavia, and for some time followed the law. Entering the service of the Church, he found favour with Paul III., who entrusted him with the government of several important towns, and in 1549 made him a cardinal. Julius III. sent him upon missions to Germany and Hungary. With Paul IV. he was out of favour, because not in sympathy with his policy, and accordingly retired to Milan. In the protracted and momentous concile that followed the death of Paul the election of Pius (Dec. 25, 1559) was due to a compromise between the Spanish and French factions.

The temperament and habit of Pius was the antithesis of his predecessor: affable, vivacious, convivial. He was, moreover, astute, diplomatic and experienced in affairs. He allowed the reform movement free course, but tried to repair certain injustices of Paul IV. (for example, releasing and reinstating Morone, who had been imprisoned on a charge of heresy), and mitigated some of his extreme decrees. But to the nephews of Paul he showed no mercy: they were charged with various crimes, condemned, upon testimony of suspicious validity, and executed on the 5th of March 1561. The Colonnii, who had been active in the prosecution, recovered Palliano. But under Pius V. judgment was reversed, the memory of the Caraffa rehabilitated, and restitution made to the family. Pius IV. himself was not guiltless of nepotism; but the bestowment of the cardinalate and the archbishopric of Milan upon his nephew, the pure and upright Carlo Borromeo, redounded to the honour of his pontificate and the welfare of the church.

With England lost to the papacy, Germany overwhelmingly Protestant, and France on the verge of civil war, Pius realized how fatuous was the anti-Spanish policy of his predecessor. He therefore recognized Ferdinand as emperor, and conciliated Philip II. with extensive ecclesiastical privileges. But subsequently, antagonized by Philip's arrogance, he inclined towards France, and gave troops and money for the war against the Huguenots.
After a suspension of ten years the council of Trent reconvened on the 15th of January 1562. Among the demands presented by the various nations were, the recognition of the equality of the episcopate, communion in both kinds, clerical marriage, and the use of the vernacular in Church services. It required all the pope's dispensations to avoid compliance on the one hand, and a breach of faith with the power and pronouncement of the Inquisition, on the other. Borromeo, however, he achieved his end. The council was dissolved on the 4th of December 1563, and its decrees and definitions confirmed by the pope (Jan. 26, 1564), who reserved to himself the sole right of interpretation. The decrees were immediately accepted by most of the Catholic states; only tardily, however, and with reservation by France and Spain. Various measures were taken for carrying the decrees into effect: residence was strictly enjoined; plurality of benefices prohibited; the Inquisition resumed, under the presidency of Ghislieri (afterwards Pius V); a new edition of the Index published (1564); and the "Tridentine creed" promulgated (Nov. 13, 1564).

After the termination of the council Pius indulged his desire for ease and pleasure, to the great offence of the rigorists. A certain fanatic, Benedetto Accolti, brooding over the pope's unworthiness, felt inspired to remove him, but his plot was discovered and punished (1565). Pius fortified Rome, and contributed much to the embellishment of the city—among other works, the church of Sta Maria degli Angeli in the Baths of Diocletian; the Porta Pia; the Villa Pia in the Vatican Gardens; and the Palace of the Conservatori. He died on the 9th of December, and was succeeded by Pius V. See Panvinio, continuator of Platina, De vita pontific. rom. (a contemporary of Pius); Ciacionius, Vitae et res gestae summarum pontific. rom. (Rome 1601-1602; also contemporary); T. Müller, Das Konklave Pius IV. (Gotha, 1886; more comprehensive than the title suggests); Ranke, Popes (Eng. trans. Austin), i. 523 seq., 528 seq.; and v. Reumont, Gesch. der Stadt Rom, iii. 2, 534 seq., 730 seq. (T. F. C.)

Pius V. (Michele Ghislieri), pope from 1566 to 1572, was born on the 17th of January 1504, in the Milanese. At the age of fourteen he became a Dominican monk. His austere life, his vehemence in attacking heresy and his rigorous discipline as prior of several monasteries proved his fitness for the work of reform, and he was appointed inquisitor in Como, where his zeal provoked such opposition as to compel his recall (1550). The chief inquisitor, Caraffa, convinced of his value, straightway sent him upon a mission to Lombardy, and in 1551 appointed him commissary-general of the Holy Office. When Caraffa became pope, Ghislieri was made bishop of Nepi and Sutri, cardinal (1557), and finally grand inquisitor, which office he discharged in a manner to make the name of "Fra Michele dell' Inquisizione" a terror. In this office he was continued by Pius IV., whom, however, he rebelled by his excessive severity, and antagonized by his censoriousness and obstinacy. But the movement which with him was so fully identified was irresistible; and, after the death of Pius IV., the rigorists, led by Borromeo, had no difficulty in making him pope (Jan. 7, 1566).

Though pope, Pius did not cease to be a monk: his ascetic mode of life and his devotions suffered no interruption. Without delay he applied himself to the work of reform. Decrees and ordinances were issued with astonishing rapidity: the papal court was rid of everything unseemly, and became a model of sobriety; prostitutes were driven from the city, or confined to a certain quarter; severe penalties were attached to Sunday desecration, profanity and animal baiting; clerical residence was enforced; conventuals were compelled to live in strict seclusion according to their vows; catechetical instruction was enjoined. A new catechism appeared in 1566, followed by an improved breviary (1568), and an improved missal (1570). The use of indulgences and dispensations was restricted, and the penitential system reformed.

Pius was the avowed enemy of nepotism. One nephew, it is true, he made cardinal, but allowed him no influence: the rest of his relatives he kept at a distance. By the constitution Admonet nos (March 29, 1567), he forbade the reinvestiture of fiefs that should revert to the Holy See, and bound the cardinals by oath to observe it. In March 1569 Pius ordered the expulsion of the Jews from the states of the Church. For commercial reasons they were allowed to remain in Rome and Ancona, but only upon humiliating conditions. In February 1571, the Umiliati, a degenerate monastic order of Milan, was suppressed, and the Inquisiteur general condemned to death. Pius V. showed no scruple in the interchange of correspondence with the Turk I. Magnifico, in an attempt upon the life of the archbishop, Carlo Borromeo.

The election of Pius to the papacy was the entrenchment of the Inquisition: the utter extinction of heresy was his darling ambition, and the possession of power only intensified his passion. The rules governing the Holy Office were sharpened; old charges, long suspended, were revived; rank offered no protection, but rather exposed its possessor to fiercer attack; none were pursued more relentlessly than the cultured, among whom many of the Protestant doctrines had found acceptance; princes and states withdrew their protection, and courted the favour of the Holy See by surrendering distinguished offenders. Cosmos de' Medici handed over Pietro Carestiachi and two years later received in reward the title of grand duke, Sept. 1569; Venice delivered Guido Zanetti; Philip II., Bartolomé de Carranza, the archbishop of Toledo. In March 1571 the Congregation of the Index was established and greater thoroughness introduced into the pursuit of heretical literature. The result was the flight of hundreds of printers to Switzerland and Germany. Thus heresy was hunted out of Italy: the only regret of Pius was that he had sometimes been too lenient. In 1567 Pius condemned the doctrines of Michael Baius, a professor of Louvain, who taught justly, being helped by faith, asserted the sufficiency of the Scriptures, and disparaged outward forms. Baius submitted, but his doctrines were afterwards taken up by the Jansenists.

The political activities of Pius were controlled by one principle, war upon the heretic and infidel. He spurred Philip II., on in the Netherlands, and approved the bloody work of Alva. He denounced all temporizing with the Huguenots, and commanded their extermination (ad intersectionem usque). While it cannot be proven that he was privy to the massacre of St Bartholomew, still his violent counsels could not fail to stir up the most savage passions. He exclaimed loudly against the emperor's toleration of Protestantism, and all but wished his defeat at the hands of the Turks. He urged a general coalition of the Catholic states against the Protestants; and yet published, in sharper form, the bull In coena domini (1568), which was regarded by these very states as an attack upon their sovereignty. One of his cherished schemes was the invasion of England and the dethronement of Elizabeth, whom he excommunicated and declared a usurper (Feb. 25, 1570); but he was obliged to content himself with abetting plots and fomenting rebellions. He did, however, effect an alliance with Spain and Venice against the Turks, and contributed to the victory of Lepanto (Oct. 6, 1571).

Thus lived and wrought Pius, presenting "a strange union of singleness of purpose, magnanimity, austerity and profound religious feeling with sour bigotry, relentless hatred and bloody persecution" (Ranke). He died on the 1st of May 1572; and was canonized by Clement XI. in 1712.

See Ciacionius, Vitae et res gestae summarum pontific. rom. (Rome 1601-1602; a contemporary of Pius); Acta sanctorum, maij, tom. i. pp. 616 seq., containing the life by Gabrino (1603), based upon an original letter by Catena (1586); von Frey, Hist. de S. P. V. (3rd ed., Paris, 1856), eulogistic; Mendham, Life and Pontificate of St Pius V. (London, 1852), a bitter polemic. The life of Pius has also been written by Fuenmayor (Madrid, 1595); by Carlo Francesco Uberti (Rome, 1712), and by T. M. Gravelot (Bologna, 1777). His letters have been edited by Catena (vide supra), Gobau (Antwerp, 1640), and a select number in a French translation, by de Potter (Paris, 1826).

Pius VI. (Giannini Angelo Braschi), pope from 1775 to 1799, was born at Cesena, on the 27th of December 1717. After taking the degree of doctor of laws he went to Ferrara and became the private secretary of Cardinal Ruffo, in whose bishopric of Ostia and Velletri he held the post of uditore until 1753. His
skill in the conduct of a mission to the court of Naples won him the esteem of Benedict XIV., who appointed him one of his secretaries and canon of St Peter's. In 1758 he was raised to the prelature, and in 1760 to the treasurership of the apostolic chamber by Clement XIII. Those who chafed under his conscientious economies cunningly induced Clement XIV. to create him cardinal-priest of San Onofrio on the 26th of April 1773, a promotion which rendered him for the time innocuous. In the four months' convivial which followed the death of Clement XIV., Spain, France and Portugal at length dropped their objection to Braschi, who was after all one of the more moderate opponents of the anti-Jesuit policy of the previous pope, and he was elected to the vacant see on the 15th of February 1775. *

His earlier acts gave fair promise of liberal rule and reform in the defective administration of the papal states. He showed discrimination in his benevolences, reprimanded Potenziani, the governor of Rome, for unsuppressed disorders, appointed a council of cardinals to remedy the state of the finances and relieve the pressure of imposts, called to account Nicolo Bischi for the expenditure of moneys intended for the purchase of grain, reduced the annual disbursements by the suppression of several pensions, and adopted a system of bounties for the encouragement of agriculture. The circumstances of his election, however, involved him in difficulties from the outset of his pontificate. He had received the support of the ministers of the Crowns and the anti-Jesuit party upon a tacit understanding that he would continue the action of Clement, by whose brief Dominus ac reedium (1773) the dissolution of the Society of Jesus had been pronounced. On the other hand the zelanti, who believed him secretly inclined towards Jesuitism, expected from him some reparation for the alleged wrongs of the previous reign. As a result of these complications Pius was led into a series of half measures which gave little satisfaction to either party; although it is perhaps largely due to him that the order was able to escape shipwreck in White Russia and Silesia; at least one juncture did he even seriously consider its universal re-establishment, namely in 1792, as a bulwark against revolutionary ideas. Besides facing dissatisfaction with this temporizing policy, Pius met with practical protests tending to the limitation of papal authority. To be sure " Febronius, " the chief German literary exponent of the old Gallican ideas, was himself led (not without scandal) to retract; but his positions were adopted in Austria. Here the social and ecclesiastical reforms undertaken by Joseph II. and his successors were opposed by the papal legates, and the pope declared that in the hope of staying them Pius adopted the exceptional course of visiting Vienna in person. He left Rome on the 27th of February 1783, and, though magnificently received by the emperor, his mission proved a fiasco; he was, however, able a few years later to curb those German archbishops who, in 1786 at the Congress at Ems, had shown a tendency towards independence. In Naples difficulties necessitating certain concessions in respect of feudal homage were raised by the minister Tannucci, and more serious disagreements arose with Leopold I. and Scipione de' Ricci, bishop of Pistola and Prato, upon the questions of reform in Tuscany; but Pius did not feel it necessary to avail himself of their system of agitation. Pistola (1786) till nearly eight years had elapsed. At the outbreak of the French Revolution Pius was compelled to see the old Gallican Church suppressed, the pontifical and ecclesiastical possessions in France confiscated and an effigy of himself burnt by the populace at the Palais Royal. The murder of the republican agent, Hugo Basseville, in the streets of Rome (January 1793) gave new ground of offence; the papal court was charged with complicity by the French Convention; and Pius threw in his lot with the league against France. In 1796 Napoleon invaded Italy, defeated the papal troops and occupied Ancona and Larino. Pius sued for peace, which was granted at Tolentino on the 19th of February 1797; but on the 31st of December of that year, in a riot created by some Italian and French revolutionaryists, General Duphot of the French embassy was killed and a new pretext furnished for invasion. General Berthier marched to Rome, entered it unopposed on the 13th of February 1798, and, proclaiming a republic, demanded of the pope the renunciation of his temporal authority. Upon his refusal he was taken prisoner, and on the 20th of February was escorted from the Vatican to Siena, and thence to the Certosa near Florence. The French declaration of war against Tuscany led to his removal by way of Parma, Placentia, Turin and Grenoble to the citadel of Valence, where he died six weeks later, on the 29th of August 1799. Pius VII. succeeded him.

The name of Pius VI. is associated with many and often unpopular attempts to revive the splendour of Leo X. in the promotion of art and public works—the words "Manuificentia Pii VI. P. M." graven in all parts of the city, giving rise amongst his impoverished subjects to such satire as the insertion of a minute loaf in the hands of Pasquin with that inscription beneath it. He is best remembered in connexion with the establishment of the museum of the Vatican, begun at his suggestion by his predecessor, and with an unpractical and expensive attempt to drain the Pontine marshes.

(W. W. R.)

PIUS VII. (Luigi Barnaba Chiaramonti), pope from 1800 to 1823, the son of Count Scipione Chiaramonti and the deeply religious Countess Ghini, was born at Cesena on the 14th of August 1740 (not 1742). After studying at Ravenna, at the age of sixteen he entered the Beneficentine monastery of St Mary in his native town: here he was known as Gregorio. Almost immediately he was sent by his superiors to Padua and to Rome for a further course of studies in theology. He then held various teaching appointments in the colleges of his order at Parma and at Rome. He was created an abbot of his order by his relative Pius VI., who also appointed him bishop of Tivoli on the 16th of December 1782, and on the 14th of February 1785, because of excellent conduct of office, raised him to the cardinalate and the see of Imola. At the death of Pius VI. the conclave met at Venice on the 30th of November 1799, with the result that Chiaramonti, the candidate of the French cardinal-archbishop Maury, who was most skilfully supported by the secretary of the conclave Ercole Consalvi, was elected pope on the 14th of November. He assumed the name of Pius, and on the 1st of that month; in the following July he entered Rome, on the 12th of August appointed Consalvi cardinal-deacon and secretary of state, and busied himself with administrative reforms. His attention was at once directed to the ecclesiastical anarchy of France, where, apart from the broad schism on the question of submission to the civil constitution of the clergy, discipline had been so far neglected that a large proportion of the churches were closed, dioceses existed without bishops or with more than one, Jansenism and clerical marriage were on the increase, and indifference or hostility widely prevailed amongst the people. Encouraged by Napoleon's desire for the re-establishment of the Roman Catholic religion in France, Pius negotiated the celebrated Concordat of 1801 in which the name of the pope was restored and was ratified by Pius on the 14th of August 1801 (see Concordat). The importance of this agreement was, however, considerably lessened by the "articles organiques" appended to it by the French government on the 8th of April 1802. In 1805 Napoleon opened negotiations to secure at the pope's hands his formal consecration as emperor. After some hesitation Pius was induced to perform the ceremony at Notre Dame and to extend his visit to Paris for four months; but in return for these favours he was able to obtain from Napoleon merely one or two minor concessions. Pius, who arrived in Rome on the 16th of May 1805, gave to the college of cardinals a rose-coloured report of his experiences; but disillusionment was rapid. Napoleon soon began to disregard the Concordat, and in 1808 he dissolved the commission. The irritation between France and the Vatican increased so rapidly that on the 2nd of February 1808 Rome was
occupied by General Miolli; a month later the provinces of Ancona, Macerata, Fermo and Urbino were united to the kingdom of Italy, and diplomatic relations between Napoleon and Rome were broken off; finally, by a decree issued from Schönbrunn on the 17th of May 1809, the emperor united the papal states to France. Piús retaliated by a bull excommunicking the invaders; and, to prevent insurrection, Miolli—either on his own responsibility, as Napoleon afterwards asserted, or by order of the latter—employed General Radet to take possession of the pope’s person.

The palace on the Quirinal was broken open during the night of July 5th, and, on the persistent refusal of Piúš to rescind the bull of excommunication and to renounce his temporal authority, he was carried off, first to Grenoble, thence after an interval to Savonna on the Gulf of Genoa. Here he steadfastly refused canonical institution to the bishops nominated by Napoleon; and, when it was discovered that he was maintaining a secret correspondence, he was deprived of all books, even of pen and ink. At length, his nerves shattered by insomnia and fever, he was willing to give satisfactory oral assurances as to the institution of the French bishops.

In May 1812 Napoleon, on the pretext that the English might liberate the pope if he were left at Savonna, caused the aged and sick pontiff to be transported to Fontainebleau. The road (from Mount Cenis Piús received the viaticum. Arriving safely, however, at Fontainebleau, he was lodged in a suite of regal magnificence to await the return of the emperor from Moscow. When Napoleon arrived, he entered into personal negotiations with the pope, who on the 25th of January 1813 ascertained to a concordat so degrading that his conscience found no relief till the 24th of March, when, on the advice of the cardinals Paca and Consalvi, he abrogated it; and on the 9th of May he proceeded to defy the emperor by declaring invalid all the official acts of the new French bishops. In consequence of the battle of Lepzig and the entry of the allied forces into France, Napoleon ordered in January 1814 that the pope be returned to Savonna for safe keeping; and the Cardinal of Vienna, the Austrian delegate to liberate the pope and give back the States of the Church. On the 19th of March Piús left Savonna, and was received with rejoicing at Rome on the 24th of May. While at the Congress of Vienna was securing the restitution of nearly all the papal territory, reaction had full swing at Rome; the Jesuits were restored; the French legislation, much of which was of great social value, was repealed; the Index and the Inquisition were revived. On his return Consalvi conducted a more enlightened and highly centralized administration, based largely on the famous Molus proprio of 1816; nevertheless the finances were in a desperate condition. Discontent centred perhaps in the Congregation of Consistory, the negotiation of a series of valuable concordats with all the Roman Catholic powers save Austria. In the latter years of Piús’s life royalty often came to Rome; the pope was very gracious to exiled kings and showed notable magnanimity toward the family of Napoleon. He also attracted many artists to the city, including the greatest sculptors of the time, one of whom, the Protestant Thorwaldsen, prepared the tomb in which repose the remains of the gentle and outstanding pontiff, who passed into rest on the 20th of August 1829. His successor was Leo XII.

Both these last have good bibliographies.

Pius VIII. (Francesco Xavier Castiglioni), pope from 1829 to 1830, who came of a notable family at Cingoli near Ancona, was born on the 20th of November 1761. He studied canon law at Rome, became vicar-general at Anagni and later at Fano, and in 1800 was appointed bishop of Montalto. Because he refused the oath of allegiance to the Napoleonic king of Italy he was carried captive to France; but in 1816 his steadfastness was rewarded by his being created cardinal-priest of Sta Maria in Trastevere; and this same year he was translated from the see of Montalto to that of Cesena. In 1821 he was made cardinal-bishop of Frascati, also grand penitentiary; and later he became prefect of the Congregation of the Index. In the conclave which followed the death of Leo XII., Castiglioni, the candidate of France, was elected pope on the 31st of March 1829. He avoided nepotism, abandoned the system of espionage employed by his predecessor, and published an encyclical condemning Bible societies and secret associations. He rejoiced over Catholic emancipation in England, recognized Louis Philippe as the king of France, and exhibited a pacific spirit in dealing with the problem of mixed marriages in Germany. Worn out with work, he died on the morning of the 1st of December 1830. His successor was Gregory XVI.

Pius IX. (Giovanni Maria Mastai-Ferretti), pope from 1846 to 1878, was born on the 13th of May 1792 at Sinigaglia, the fourth son of Count Jerome and Countess Catherine Vollaz; the family of Mastai was of ancient descent, and the title of count came to it in the 17th century, while later the elder branch, allied by marriage with the Ferretti family, took that name in addition. He spent some time at the College of Priests in Volterra, and then proceeded to Rome with the intention of entering the pontifical guard as an officer. In spite of his good connexions, he was disappointed in this aim as it became known that he suffered from epilepsy. The malady, however, was surmounted; and in 1819 he was ordained priest. After ministering for some time in his native town, he accompanied Cardinal Muzzi to Chile (1834). On his return he was entrusted by Leo XII. with the direction of the Roman hospital of San Michele: in 1830 he received the archbishopric of Spoleto, in 1832 the bishopric of Imola, and in 1840 Gregory XVI. created him a cardinal, with the title Santi Pietro e Mareccello.

On the death of Gregory XVI. (June 1, 1846) the College of Cardinals met in conclave on the 14th of June. But their deliberations were destined to last but a short while; for, on the 16th of June, Cardinal Mastai Ferretti had already obtained the requisite two-thirds majority, and ascended the papal chair under the title of Pius IX. In his various capacities he had gained enormous popularity: he had shown himself to be of a kindly disposition and a zealous churchman, and his reputation for piety and tact stood high; he possessed, too, a winning personality and a handsome presence.

The reign of Pius IX. began at an extremely critical time. The problem of the government of the Papal States, transmitted to him by his predecessor, stood in urgent need of solution, for the actual conditions were altogether intolerable. The irritation of the populace had risen to such a pitch that it found vent in revolts which could only be quelled by the intervention of foreign powers; and the ferment in the dominions of the Church was accentuated by the fact that the revolutionary spirit was in the ascendant in all the states of Europe. The proclamation of a universal amnesty for all political offenders made an extremely impressive impression on the people; and Pius at once instituted preparations for a reform of the administration, the judicature and the financial system. The regulations affecting the censorship were mitigated, and a breath of political liberalism vitalized the whole government. Pius at once acquired the reputation of a reforming pope. But the prestige so gained was not sufficient to calm the people permanently, and two demands were urged with ever increasing energy—a share in the government and a national,
Italian policy. The problem of giving the people a due share in the government was one of peculiar difficulty in the papal states. It was not simply a question of adjusting the claims of monarch and subject; it was necessary, at the same time, to consult the clergy—who, till then, had held all the more important offices in their own hands—from their dominant position, or at least to limit their privileges. That the clerical character of the administration could not be indefinitely maintained was plain enough, it would seem, to any clear-thinking statesman: for, since the restoration of the papal state in 1814, the pernicious effects of this confusion of the spiritual and the secular power could no longer be denied. But Pius IX. lacked the courage and perspicacity to draw the inevitable conclusions from these premises; and the higher clergy at Rome were naturally opposed to a policy which, by inaugurating the administration, would have deprived them of the power and privileges they had so long enjoyed. In these circumstances it is not surprising that the pope, while making concessions to his people, did so with reservations which, so far from restoring peace, served only to aggravate the turmoil.

By a motu proprio of the 2nd of October 1847 the government of the city of Rome was reorganized and vested in a council of 100 members, not more than four of whom were to be clerics. But the pope reserved to himself the right of nominating the first members, and the new senate was only later to have the right of filling up vacancies by co-optation. The institution of a state council (consulato) was announced on the 19th of April 1847; and on the 14th of October it was called into existence by a motu proprio. It consisted of 24 councillors, who were to be selected from the roll of the cardinals and other prelates to be submitted by the province and assemblies. A cardinal and one other prelate were to be at its head. The consulta was to be divided into four sections, dealing with (1) legislation, (2) finance, (3) internal administration, (4) the army and public works. Matters of importance were, however, to be submitted to the College of Cardinals, after being debated in the consulta. A motu proprio of the 29th of December altered the constitution of the ministerial council. Nine mutually independent ministries were formed, and the principle of the responsibility of the ministers was established: but all the positions were filled by clerics.

The agitation for constitutional government was urgent in the demand for further concessions; but they came too late. On the 12th of February a proclamation of the pope transferred three powers from the pope to the clergy. On the 15th the revolution in Paris nullified the nullification. At the formation of the Antonelli ministry (March 11), only the three departments of foreign affairs, finance, and education, were reserved by the clergy; while the remaining six were entrusted to laymen. On the 14th of March 1848 Pius took the last step, and published a constitution (Fundamental Statute for the Secular Government of the States of the Church). Two chambers were to be formed. The first (alto consiglio) consisted of members nominated for life by the pope; the second, of a hundred elected deputies. The laws adopted by these two chambers had first to undergo the scrutiny of the College of Cardinals, before being submitted to the pope for his assent or rejection. Ecclesiastical, or even secular, legislation might have been invalid. On the 3d of June the pontiff by a motu proprio, took away from the parliament, which was further required to abstain from the enactment of laws conflicting with the discipline of the Church, and from criticism of the diplomatic and religious relations of the Holy See with foreign powers.

The utility of this constitution was never tested; for the demand for an extension of popular rights was now eclipsed by a still more passionate aspiration towards the national unity of Italy. This nationalistic movement at once took head against Austria. On the 18th of March the revolution broke out in Milan, and King Albert of Sardinia undertook the conduct of the war against the emperor. When news of the events at Milan reached Rome the populace was swept away in a whirlwind of enthusiasm: the Austrian embassy was mobbed; the imperial arms, surmounting the main gate of the palace, were torn down; and great troops of volunteers clamoured to be led against Austria. Pius was carried away at first on the flood-tide of excitement, and seemed after his proclamation of the 30th of March, on the point of conferring his blessing upon the war against Austria. But the course of political events during the next few weeks damped his ardour. When, on the 29th of April, in his allocution to the cardinals, he proclaimed the papal neutrality, the Romans received his vacillation as a sign of treachery; and the storm, precluded from discharging its fury on Austria, broke over his head. When the ministry in power resigned office on the 15th of May, the Manzoni administration was formed, only one desk being included. Manzoni himself, whose writings were on the Index, had little sympathy with the pope, and did all that was possible to complete the secularization of government in the States of the Church. He received his dismissal on the 1st of August, and was followed by Count Fabbrini, then by Count de Rossi, who made the last attempt to restore order by a moderate liberal policy. On the 15th of November, as he was about to open the Chambers, he was assassinated on the staircase leading to the hall of session. A state of anarchy ensued: armed bands gathered before the Quirinal, and attempted to storm it. To avoid further bloodshed the pope was compelled to assent to the formation of a radically democratic ministry under Galetti. The Swiss, who composed the papal guard, were disbandued; and the protection of the pontiff was transferred to the civil militia; in other words, Pius IX. was a prisoner. On the evening of the 24th of November he contrived by the aid of the French and Bavarian ambassadors—the due d'Harcourt and Count Spaur—to leave the palace unobserved, in the dress of a common priest, and to reach Gaeta in the kingdom of Naples. From this refuge he issued a breve on the 27th of November, protesting against the sacrilege practised on himself, declaring all actions forced upon him null and void, and appointing another pope to carry on the government in his absence. Since the Chamber declined to recognize this step, and the pope was equally resolute in refusing to hold any intercourse with the deputation which it despatched to him, a supreme Giunta was provisionally created by the Chamber on the 11th of December to discharge all the functions assigned to the executive power by the constitution. On the 17th of the same month Pius made a public protest; and, as soon as the elections for a national assembly were announced, he forbade any participation in them, menacing the disobedient with the penalties of the Church (Jan. 1, 1849). The elections, however, were held; and on the 9th of February the new Diet decreed the abolition of the Pope, the evacuation of a Roman republic. Pius answered by a protest dated the 14th of February. All the ecclesiastical property of the Roman state was now declared to be vested in the republic; convents and religious edifices were requisitioned for secular purposes; benevolent institutions were withdrawn from clerical influence; and church establishments were deprived of the right to realize their possessions. In the beginning of December Pius had already appealed to the European powers for assistance; and on the 7th of February 1849 it was resolved in the Consistory to approach officially France, Austria, Spain and Naples, with a view to their armed intervention. The French republic, under the presidency of Louis Napoleon, was the first state to throw troops upon the territory of the Pope. On the 3rd of March an army of 7,000 men, under General Cavaignac, entered Rome--before Civita Vecchia; only to be defeated at first by Garibaldi. But, after receiving reinforcements, he prosecuted the war successfully, and made his entry into Rome on the 3rd of July; while, in the early part of May an Austrian army advanced into the north of the papal states. On the 14th of July Oudinot proclaimed the restoration of the pontifical dominion; and, three days later, Pius IX. issued a manifesto entrusting the government to a commission appointed by himself.

On the 12th of April 1850 Pius returned to Rome, supported by foreign arms, embittered, and hostile hencforth to every form of political liberalism or national sentiment. In Gaeta he had mentally cut himself loose from all ideas of progress, and had thrown himself into the arms of the Jesuits. His subsequent policy was stamped by reaction. Whether it might have been possible to avoid the catastrophe of 1848 is a difficult question. But there can be no question whatever that the policy which
PIUS (PAPES) 689

Pius now inaugurated, of restoring the old pre-revolutionary conditions, sealed the fate of the temporal dominion of the papacy. He made no attempt to regain the estranged affections of the populace, and took no measures to liberate himself and his subjects from the incubus of the last few years. He even sought to exact vengeance for the events of that period: the state officials, who had compromised themselves, lost their offices; and all grants in aid were forfeited if the recipients were discovered by the secret commissions (consiglio di censura) to have taken part in the revolutionary movement. The tribunals extorted declarations on the part of witnesses by flogging, deprivation of food, and like methods of torture. In many cases the death sentence was executed at their instance, though the guilt of the accused was never established. The system of precautionary arrest, as it was termed, rendered it possible for any man to be thrown into prison, without trial and without verdict, simply on the ground that he lay under suspicion of plotting against the government. The priests, who usurped the judicial function, displayed such cruelty on several occasions that officers of the Austrian army were compelled to record a protest. The consequence of these methods was that every victim—innocent or guilty—ranked as a martyr in the estimation of his fellow-citizens. A subsidiary result was the revival of brigandage, which found a suspicious degree of support among the people. Corruption was rampant among the officials; the police were accused of illicit bargaining with criminals; and nothing but contempt was entertained for the papal army, which was recruited from the dregs of humanity. To this was added a disastrous financial administration, under which the efficiency and credit of the country sank to appalling depths. The system of taxation was calculated with a view to relieving the Church and the clergy, and imposing the main burden upon the laity. In this department the family of Cardinal Antonelli seems to have played a fatal part. The secretary of state was born in humble circumstances: when he died he left a fortune of more than 100,000,000 lire, to which a daughter succeeded in establishing her claim. His brother Felippo was president of the Roman Bank, and his brother Luigi the head of the Annona—an office created to regulate the import of grain. The pope himself had neither the will nor the power to institute searching financial reforms; possibly, also, he was ignorant of the facts.

The mismanagement which obtained in the papal dominions could not escape the observation of the other powers. As early as the Congress of Paris in 1856 the English ambassador, Lord Clarendon, had directed an annihilating criticism against the government of the pontiff; and a convincing proof of the justice of his verdict was given by Pius himself, in his treatment of the famous Mortara case. A Jewish boy ofOrigin in Milan was taken from his parents in Rome and the rite of baptism performed on him without their knowledge or consent. The pope flatly refused to restore the “Christian” to his Jewish parents, and turned a deaf ear both to the protest of public opinion and the diplomatic representations of France and England. The sequel to this mode of government was that the growing emigration of the subjects of the Church came to be sympathized with outside the bounds of Italy, and the question whether the secular authority of the papacy could be allowed to continue became a much-debated problem. Even the expression of the doubt was symptomatic. In 1859 appeared an anonymous brochure, Le Pape et le congrès, composed by Laggeronniére, the friend of Napoleon III., in which it was proposed to ensure the pope an “un envie à considérable” and the city of Rome, but to relieve him of a political task to which he was not competent. In 1861 another anonymous pamphlet, Pro causa Italicæ ad episcopos catholici, was published in Florence, advocating the ecclesiastico-political programme of Cavour; and the pope was horrified when he discovered that it came from the pen of Passaglia, the professor of dogmatic theology. In spite of all, the national idea gained strength in Italy, and the movement towards unity found powerful champions in King Victor Emmanuel of Sardinia and his great statesman Cavour. Free scope was given when the understanding between the two powers protecting the papal state—France and Austria—broke down. So soon as Napoleon and Cavour had come to an agreement war ensued, France and Sardinia being ranged against Austria (1859). The result was that Austria lost the greater part of her Italian possessions, while the pope also forfeited two-thirds of his dominions. By the war of 1866, in which Italy fought on the Prussian side, Victor Emmanuel gained Venice in addition; so that the States of the Church now formed the last remaining obstacle to complete national unity. In September 1864, France—who had been the protectress of these states since 1849—had concluded a treaty with Victor Emmanuel, undertaking to withdraw her garrison from Rome in two years time; while, on his part, the king agreed to abstain from any attack on the papal dominions, and to guarantee the safety of the pope and the patriaminium Poeti. The emperor Napoleon had, in point of fact, recalled his troops in 1866; but in 1867, when Garibaldi crossed the frontiers of the papal state at the head of his volunteers, he declared the treaty violated and again threw his regiments into Rome. Three years later the time came when he could employ his arms more advantageously elsewhere, and after the outbreak of the war with Germany Rome was evacuated. The news that the French Empire had fallen produced an electrical effect in Italy: the Italian parliament called on the king to occupy Rome; on the 8th of September Victor Emmanuel crossed the borders; and on the 20th of September the green-white-and-red of the tricolour floated over the Capitol. The protests of Pius IX. remained unheeded, and his attempts to secure another foreign intervention met with no success. On the 2nd of October Victor Emmanuel instituted a plebiscite in Rome and the possessions of the Church to decide the question of annexation. The result of the suffrage was that 153,681 votes were given in favour of union with Italy, and 1507 against the proposed incorporation: that is to say only the direct dependants of the Vatican were opposed to the change. The papal state was now merged in the kingdom of Italy, which proceeded to define its diplomatic relations with the Holy See by the law of the 13th of May 1871 (see ITALY: History).

In his capacity as head of the Church, Pius IX., adhered to the principles of the Ultramontanist party, and contributed materially to the victory of that cause. The political reaction which followed the revolutionary era in most quarters of Europe offered a favourite soil for his efforts; and in several countries he found it possible to regulate the relations between Church and state from the standpoint of the curia. In 1851 he concluded a concordat with Queen Isabel II. of Spain, proclaiming Roman Catholicism the sole religion of the Spanish people, to the exclusion of every other creed (art. 1); and we find the limits of the curia extended to the republic of Ecuador (1862). A third concordat, negotiated with the emperor Francis Joseph I. of Austria (1855), entrusted the supervision of schools and the censorship of literature to the clergy, recognized the canon law, and repealed all secular legislation conflicting with it. France came into line with the wishes of the pope in every respect, as Napoleon needed clerical support in his political designs. Even in Germany he found no resistance; on the contrary, he was able to secure advantageous compacts from individual states (Hesse, 1854; Württemberg, 1857). In fact, the growing tendency to romanize Catholicism—to bring it, that is to say, into close connexion with Rome, and to a state of dependency on the guidance and instructions of the curia—made special progress in Germany.

Among the most important acts of Pius IX. must be counted his proclamation of the dogma of the Immaculate Conception of the Virgin Mary, by the bull Ineffabilis Deus, on the 8th of December 1854. In this bull the preservation of Mary from every stain of hereditary sin, in the first moment of her conception, was declared to be a divinely revealed truth, which consequently demanded universal acceptance (see IMMACULATE CONCEPTION). By this means a view, which till then had been no more than a pious belief, was elevated into a dogma to be held de fide; though grave doubts on the subject had always been entertained, even in the midst of the Church itself. For the inner life of that
Church this solution of the controversy was of great significance, and created a desire for further doctrinal decisions on the Virgin Mary—her resurrection and ascension. But the procedure of Pius IX. proved of far-reaching importance from another point of view. True, he had taken the opinion of the bishops on the subject, and had received the assent of a large majority; none the less, the verdict was pronounced by himself alone, not by an ecumenical council. Thus, by arrogating the function formerly exercised by the ecumenical council, he virtually laid claim to the infallibility which had always been regarded as inherent only in the doctrinal pronouncements of such a council: in other words, he availed himself of a privilege not accorded to him till the 18th of July 1870.

Though the Marian dogma of 1854 received, with very few exceptions, an enthusiastic welcome in Roman Catholic circles, another measure of the pope, ten years later, excited a painful sensation even among the orthodox members of the Church. As reigning sovereign of the papal states Pius IX. had passed through a "liberal period": as head of the Church, he had never been liable to attacks of liberalism. Nevertheless, his return from exile left its mark on his spiritual administration. For from this period onwards he deliberately and stubbornly set his face against the influence of modernism on ecclesiastical life; showed his displeasure at and distrust of the scientific theology and philosophy which marked a moderate advance (Günther, Frohschammer and Döllinger); and, entrenched in the stronghold of medieval ideals, combated the transformations of the new order of society, and the changes in the relationship between Church and state, which obtained in most countries of Europe since the French Revolution. After long and careful consultation, the adverse criticisms which he had expressed on various occasions were published on the 8th of December 1864, together with the encyclical Quanta cura, under the title Syllabus definitionis errorum (see SYLLABUS). In this Pius claimed for the Church the control of all culture and all science, and of the whole educational system. He rejected the liberty of faith, conscience and worship enjoyed by other creeds; and bade an easy farewell to the idea of tolerance. He claimed the complete independence of the Church from state control; upheld the necessity of a continuance of the temporal power of the Roman See; and finally, in the last clause, declared that "the pontiff neither can be nor ought to be reconciled with progress, liberalism and modern civilization." The publication of this syllabus created a profound impression: for it declared war on modern society, and committed the papacy to the principles of Ultramontanism (q.v.). But, as any attempt to translate its precepts into practice would entail a disastrous conflict with the existing régime as established by the Concordat of 1850, the Romans, who had frequently shown a tendency to belittle the significance of the manifesto and to deny that its rules are absolutely binding. But these well-meant explanations, however comprehensible, are refuted by the unequivocal pronouncements of Pius IX., Leo XIII., and many recognized ecclesiastical authorities—e.g. Cardinal Manning, archbishop of Westminster, who described the syllabus as an emanation from the highest doctrinal authority in the Church.

The zenith of Pius's pontificate was attained on the 18th of July 1870 when the Vatican council proclaimed the infallibility of the pope and the universality of his episcopate, thus elevating him to a pinnacle which none of his predecessors had reached and at the same time fulfilling his dearest wish. That, personally, he laid great stress on the acceptance of the dogma, was a fact which he did not attempt to conceal during the long preliminary deliberations of the council; and his attitude was a not inconsiderable factor in determining its final resolutions. But the loss of the papal states, immediately afterwards, was a blow from which he never recovered. Whenever he brought himself to speak of the subject—and it was not rarely—he repeated his protest in the bitterest terms, and, to the end of his days, refused to be reconciled with the "sacred" king of Italy. When, in Germany, the situation created by the Vatican council led to the outbreak of the Kulturkampf, Pius IX. failed to display the tact peculiar to his successor. For, in the encyclical Quod nunquam (Feb. 5, 1875), he took the rash step of declaring invalid the Prussian laws regulating the relationship between Church and state—the only result being that the feud was still further embittered.

In these later years the dark days of his "captivity" were amply compensated by the proofs of reverence displayed by Roman Catholic Christianity, which accorded him magnificent ovations as his period of jubilee began to fall due. The twenty-fifth anniversary of his pontificate was celebrated with great splendour on the 20th of June 1871; for he was the first pope who had thus reached the traditional "years of Peter." In 1872 his 60th birthday gave occasion for new demonstrations; and 1875 was a so-called "year of jubilee." Finally, in 1877, the fifty years of his priesthood were completed: an event which brought him innumerable expressions of loyalty and led to a great manifestation of devotion to the Holy See from all the Roman Catholic world. On the 7th of February 1878 Pius IX. died. His successor was Leo XIII.
PIZZICATO—PLACENTA

under Alonzo de Ojeda, by whom he was entrusted with the charge of the unfortunate settlement at San Sebastian. He accompanied Balboa (whom he afterwards helped to bring to the block) in the discovery of the Pacific; and under Pedrarias d’Avila he received a repartimiento, and became a cattle-farmer at Panama. Here in 1522 he entered into a partnership with a priest named Hernando de Luque, and a soldier named Diego de Almagro, for purposes of exploration and conquest towards the south. Pizarro, Almagro and Luque afterwards renewed their compact in a more solemn and explicit manner, agreeing to conquer and divide equally among themselves the opulent empire they hoped to reach. Explorations were then undertaken down the west coast of South America, in which Pizarro, though left for months with but thirteen followers on a small island without ship or stores, persisted till he had coasted as far as about 9° S. and obtained distinct accounts of the Peruvian Empire. The governor of Panama showing little disposition to encourage the adventurers, Pizarro resolved to apply to the sovereign in person for help, and with this object sailed from Panama for Spain in the spring of 1528, reaching Seville in early summer. Charles V. was won over, and on the 26th of July 1529 was executed at Toledo the famous capitulation, by which Pizarro was upon certain conditions made governor and captain-general of the province of New Castile for the distance of 200 leagues along the newly discovered coast, and invested with all the authority and prerogatives of a viceroy, his associates being left in wholly secondary positions. One of the conditions of the grant was that within six months Pizarro should raise a sufficiently equipped force of two hundred and fifty men, of whom one hundred might be drawn from the colonies; as he could not make up his due complement he sailed clandestinely from San Lucar in January 1530. He was afterwards joined by his brother Hernando with the remaining vessels, and when the expedition left Panama in January of the following year it numbered three ships, one hundred and eighty men, and twenty-seven horses. The subsequent movements of Pizarro belong to the history of Peru (q.v.). After the final effort of the Incas to recover Cuzco in 1536-37 had been defeated by Diego de Almagro, a dispute occurred between Pizarro and Almagro respecting the limits of their jurisdiction. This led to battle; Almagro was defeated (1538) and executed; but his supporters conspired, and assassinated Pizarro on the 26th of June 1541.

PIZZICATO (from Ital. pizzicare, to pluck or twitch), a term in music for a direction to the players of stringed instruments, that the passage so marked is to be played by plucking the strings with the fingers instead of using the bow.

PIZZO, a seaport of Calabria, Italy, in the province of Catanzaro, 72 m. by rail N.E. of Reggio, situated on a steep cliff overlooking the Gulf of Santa Eufemia, 351 ft. above sea-level. Pop. (1901), 9172. It has an old castle, in which Joachim Murat, ex-king of Naples, was shot on the 13th of October 1815. The people engage in tunny- and coral-fishing. In 1783 the town was almost destroyed by an earthquake, and it suffered some damage from the same cause in 1905.

PLACARD (15th cent. Fr. placari, from plaquier; mod. planquer, to plaster), a bill or poster pasted or affixed to a wall or in any prominent position for the purpose of giving notice to the public of a proclamation, police or other regulations, or of forthcoming events or the like.

PLACE (through Fr. from Lat. plateo, street; Gr. παλαις, wide), a definite position in space, whether of limited or unlimited extent, situation or locality; also position in a series or rank; or an office, or employment, particularly one in the service of a government. Special applications are to an open space in a town, a group of buildings, row of houses, or as the name of a residence or manor-house. In certain cases this latter use accounts for the occurrence of parts of a town being known as Place, e.g. Ely Place in London, formerly the site of the town residence of the bishops of Ely. A "place of arms" (Fr. place d'armes), in fortification, means the wide spaces (suitable for the assembly of troops for a sortie) made by the salients and re-entrants of the covered way. The phrase is also used in a strategic sense to express an entrenched camp or fortress in which a large army can be collected under cover previous to taking the field.

PLACENTA (Lat. for a cake), in anatomy, the organ by which the embryo is nourished within the womb of its mother. When the young one is born the placenta and membranes come away as the "afterbirth." In human anatomy the organ is a circular disk about seven or eight inches in diameter and one and a quarter inches in thickness at its centre, while at its margin it is very thin and is continuous with the foetal membranes. It weighs about a pound.

In order to explain the formation of the placenta it is necessary to encroach to some extent on the domain of physiology. Before each menstrual period, during the child-bearing age of a woman, the mucous membrane of the uterus hypertrophies, and, at the period, is cast off and renewed, but if a fertilized ovum reaches the uterus the casting off is postponed until the birth of the child. From the fact that the thickened mucous membrane lining the interior of the uterus is cast off sooner or later, it is spoken of as the "decidua." The fertilized ovum, on reaching the uterus, sinks in and embeds itself in the already prepared decidua, and, as it enlarges, there is one part of the decidua lying between it and the uterine wall ("decidua serotina " or "basalis "), one part stretched over the surface of the enlarging ovum ("decidua reflexa " or "capularis ") and one part lining the rest of the uterus ("decidua vera ") (see fig. 1.)

From A. H. Young and A. Robinson, in Cunningham's Text-Book of Anatomy.}

![Diagram of the placenta](https://via.placeholder.com/150)

**Fig. 1.—Diagram representing a very young human ovum almost immediately after its entrance into the decidua, and whilst the place of its entrance is still covered with a plug of fibrin. The ectoderm has already proliferated and embraced spaces which contain maternal blood and are continuous with the maternal blood-vessels.**

It is the decidua basalis which is specially interesting in considering the formation of the placenta. That part which is nearest the ovum is called the "stratum compactum," but farther away the uterine glands dilate and give a spongy appearance to the mucous membrane which earns this particular label the name of "stratum spongiosum." Processes grow out from the surface of the ovum which penetrate the stratum compactum of the decidua basalis and capularis and push their way into the enlarged maternal blood sinuses; these are the "chorionic villi." Later, the "allantoic" or "abdominal stalk" grows from the mesoderm of the hind end of the embryo into the chorionic villi which cover the decidua basalis, and in this blood-vessels pass which push their way into the maternal blood sinuses. Eventually the original walls of these sinuses, together with the false amnion, disappear, and nothing now separates the maternal from the foetal blood except the delicate walls of the foetal vessels covered by some nucleated noncellular tissue, known as syncytium, derived from the chorionic epithelium, so that the embryo is able to take its supply of oxygen and materials for growth from the blood of its mother and to give up carbonic acid and excretory matters. It is the gradual enlargement of the chorionic villi in the decidua basalis together with the intervillous maternal blood sinuses that forms the placenta; the decidua capularis and vera eventually become pressed
The allantoic stalk elongates enormously, and in its later stages contains two arteries (umbilical) and only one vein (owing to the obliteration of the right one) embedded in some loose connective tissue known as "Wharton's jelly." At first the stalk of the yolk-sac is quite distinct from this, but later the two structures become bound up together (see fig. 2), after which they are known as the "umbilical cord." A distinction must be made between the allantoic stalk and the allantois; the latter is an outgrowth of the hind end of the mesoderm or primitive alimentary canal, which in the human subject only reaches a little way toward the placenta. The allantoic stalk is the mass of mesoderm containing blood-vessels which is pushed in front of the allantois and, as has been shown, reaches and blends with the decidua basalis to form the placenta.

For further details see Quain's Anatomy, vol. i. (London, 1898); and, for literature, O. Hertwig's Handbuch der Entwickelungslehre (Jena).

Comparative Anatomy.—If the placenta is to be regarded as a close union between the vascular system of the parent and embryo, the condition may be found casually scattered throughout the phylum of the Chordata. In such a very lowly member of the phylum as Salpa, a placenta is formed, and the embryo is nourished within the body of its parent. In some of the viviparous sharks, e.g. the blue shark (Carcharias), the yolk-sac has ridges which fit into grooves in the wall of the oviduct and allow an interchange of materials between the maternal and foetal blood. This is an example of an "umbilical placenta." In the viviparous bennies (Zebras viviparus), among the teleostean fishes, two or three hundred young are nourished in the hollow ovary, which develops vili secreting nutritive material. Among the Amphibia the alpine salamander (Salamandra atra) nourishes its young in its oviducts until the gilled stage of development is past, while in the Reptilia the young of a viviparous lizard (Seps chalcedis) establish a communication between the yolk-sac anteriorly and the allantois posteriorly, on the one hand, and the walls of the oviduct on the other. In this way both an umbilical and an allantoic placenta are formed.

The mammals are divided into Placentalia and Aplacentalia; in the latter group, to which the monotremes and most marsupials belong, the ova have a great deal of yolk, and the young, born in a very immature condition, finish their development in their mother's pouch; but although these mammals have no allantoic placenta there is a connection between the walls of the yolk-sac and the uterine mucous membrane, and so an umbilical or omphalic placenta exists. The name Aplacentalia therefore only means that they have no allantoic placenta. Among the Placentalia the umbilical and allantoic placentae are sometimes confluent, and are thus, as in the case of the hedgehog, the bandicoot and the mouse. In most of the lower placental mammals the allantois is much more developed than in man, and the most primitive type of placenta is that in which villi are formed over the whole surface of the chorion projecting into the decidua of the tubular cornu of the uterus. This is known as a "diffuse placenta," and is met with in the pangolin, pig, hippopotamus, camel, chevrotain, horse, rhinoceros, tapir, and whale. When the villi are collected into a number of round tubules, as in most ruminants, the type is spoken of as a "cotyledonal placenta," and an intermediate stage between this and the last is found in the giraffe.

In the Cervidae, elephant, procavia (Hyrax) and aardvark (Orycteropus), there is a "zonal-placenta" which forms a girdle round the embryo. In sloths and lemurs the placenta is dome-shaped, while in rodents, insectivores and bats, it is a ventral disk or closely applied pair of disks, thus differing from the dorsal disk of the ant-eater, armadillo and higher Primates, which is known as a "metasicoidal placenta." It will thus be seen that the form of the placenta is not always a trustworthy indication of the systemic position of its owner. In the diffuse and cotyledonal placentae the villi do not penetrate very deeply into the decidua, and at birth are simply withdrawn, the decidua being left behind in the uterus; in these placentae are spoken of as non-deciduate while other kinds are deciduate.

PLAGIARISM, an appropriation or copying from the work of another, in literature or art, and the passing off of the same as original or without acknowledgment of the real authorship or source. The Lat. plagiarus meant a kidnapper, stealer or abductor of a slave or child, though it is also used in the modern sense of a literary plagiarist or purloiner by Martial (I. 53, 9). The word plagiarism is used in the Digest of the offence of kidnapping or abduction, and the ultimate source is probably to be found in nagra, nagra, cognate with Gr. ἀναθεόπ, weep,plaint. The idea of plagiarism is developed with greater modern, and has grown up with the increasing sense of property in works of the intellect. (See Copyright.)

PLAGIOCLASE, an important group of rock-forming minerals, constituting an isomorphous series between albite, or soda-felspar and anorthite, or lime-felspar. Intermediate members are thus soda-lime-felspars, which in their crystallographical, optical and other physical characters vary progressively with the chemical composition between the two extreme albitic (NaAlSi3O8) and anorthite (CaAl2Si2O8). This variation is continuous in the series, but specific names are applied to members falling between certain arbitrary limits, viz.: Albite, Ab (=NaAlSi3O8); Oligoclase, AbAn to AbAn; Andesine, AbAn to AbAn; Labradorite, AbAn to AbAn; Bytownite, AbAn to AbAn; Anorthite, An (=CaAl2SiO8).

All the membra placentae are sometimes confluent, forming an anorthic (triclinic) system. They possess a perfect cleavage parallel to the basal pinacoid P (cox) and a somewhat less pronounced cleavage parallel to the pinacoid M (ote). The angle between these two cleavages varies from 85° to 24° in albite to 85° go in anorthite. It was on account of the oblique angle between the cleavages that A. Breithaupt in 1847 gave the name plagio-clase (Gr. plagio-, oblique, and κλίτος, to cleave) to these felspars, to distinguish them from the orthoclase felspar in which the corresponding cleavage angle is a right angle. It should be noted that the potash—-and potash-soda-felspars, microcline (g.) an anorthoclasie, though also anorthite, are not included in the plagio-clase series of soda-lime-felspars. Crystals are
usually tabular in habit, parallel to the plane $M$, as shown in the accompanying figures; sometimes, however, they are flattened parallel to $P$, then with a characteristic habit of polyhedral variety of albite; microcrystalline crystals forming the ground-mass of volcanic rocks are usually elongated in the direction of the edge between $P$ and $M$.

Twinning is an important character, which is almost invariably present and affords a ready means of distinguishing the plagioclases from other feldspars. Most frequent is the twinning according to the $a$-axis law with $M$ as twin-plane.

One half of the twin is turned through $180^\circ$ about the normal to this plane and the two portions are united along the same plane (for figures of twinned crystals see Albite). The basal planes of the two portions are inclined to each other at a patient or re-entrant angle of $2^\circ$ to $12^\circ$ in albite and $8^\circ$ to $20^\circ$ in anorthite. This twinning is usually polytwin, being many times repeated, and giving rise to numerous thin lamellae, which are the cause of the fine striations on the cleavage planes $P$ and parallel to the edge $PM$, so characteristic of the plagioclases as seen in hand specimens. When viewed in polarized light, thin sections of twinned crystals show a very characteristic banded structure parallel to $M$. A second twinning is known as the pericline-law, because of its frequent occurrence in pegmatite. Here, the $a$ axis is turned through $180^\circ$ about the crystallographic axis $b$ and the plane of composition is the rhombic section: the latter is a plane which intersects the prism faces $I$ and $L$ in a rhomb; it is not a possible face of the crystal in any position varying in the different feldspars. In addition to being twinned according to these two laws, plagioclase may also be twinned on the Carlsbad-, Baveno- and Manebach-laws, as in orthoclase (g.p.).

* Angles measured to the edge $PM$.

The optical characters of the plagioclases have been the subject of much study, since they are of great value in determining the constituents of rocks in thin sections under the microscope. The mean indices of refraction and the angles of extinction on the $P$ and $M$ cleavages are given in the accompanying table. The meaning of the $+\,$ and $-\,$ directions will be seen from the figure, where the face $P$ slopes from left to right, i.e. the angle between the normals to the faces lettered $P$ and $M$ is less than $90^\circ$. The extinction angles on other faces, or in sections of known orientation in the crystal, also give constants of determinative value: for example, in sections perpendicular to the plane $M$ the extinctions, which in crystals twinned according to the albite-law are symmetrical with respect to this plane, reach the maximum value given in the table. Not only do the directions of extinction (axes of light-elasticity) vary in the different species, but also the optic axial angle, so that while albite is optically positive, anorthite is negative, and a member near adesine has an axial angle of $90^\circ$. The figures seen in a parallelized light through the $P$ and $M$ cleavages are characteristic of the different species. A detailed summary of the optical characters and their employment in determinative analysis is given by H. Rosenbusch, Mikroskopische Physiographie der Mineralien und Gesteine (4th ed. Stuttgart, 1905).

The plagioclases occur as primary constituents of igneous rocks of almost every variety and are also frequent as secondary minerals in metamorphic rocks. Albite and oligoclase are more characteristic of acidic rocks, whilst the basic members at the anorthite end of the series are characteristic of rocks containing less silica.

The composition may, however, vary from one crystal to another, so that crystals of different composition may exist in the same crystal and even in the same crystal from different parts. One method of determining the composition of a plagioclase is by X-ray analysis, for which purpose the X-ray apparatus of Buerger has been adapted to the study of feldspars.

For further particulars regarding individual species and their modes of occurrence, see Adesine; Anorthite; Bytownite; Laboratory Analyses; Oligoclase.

---

**PLAGUE** (in Gr. ὅξαυη; in Lat. pestis, pestilenta), in medicine, a term given to an epidemic disease causing a great mortality, and used in this sense by Galen and the ancient medical writers, but now confined to a special disease, otherwise called Oriental, Levantine, or Bubonic Plague, which may be sharply defined as a specific infectious fever, one variety being characterized by buboes (glandular swellings) and carbuncles. This definition excludes many of the celebrated pestilences recorded in history—such as the plague of Athens, described by Thucydides; that not less celebrated one which occurred in the reign of Marcus Aurelius and spread over nearly the whole of the Roman world (A.D. 164-180), which is referred to, though not fully described, by the contemporary pen of Galen; and that of the 3rd century (about 253), the symptoms of which are known from the allusions of St Cyprian (Sermon de mortaliitate). There is a certain resemblance between all these, but they were very different from Oriental plague. "Plague" was formerly divided into two chief varieties: (1) mild plague, *pestis minor*, larval plague (*Radcliffe*), *peste fruste*, in which the special symptoms are accompanied by little fever or general disturbance; and (2) ordinary epidemic or severe plague, *pestis major*, in which the general disturbance is very severe. Cases which are rapidly fatal from the general disturbance without marked local symptoms have been distinguished as fulminant plague (*pestis siderans, peste foudroyante*).

*History up to 1850.—The first historical notice of the plague is contained in a fragment of the physician Rufus of Ephesus, who lived in the time of Trajan, preserved in the Collections of Oríobius.² Rufus speaks of the buboes called pestilential as being specially fatal, and as being found chiefly in Libya, Egypt and Syria. He refers to the testimony of a physician Diosiunius, who lived probably in the 3rd century B.C. or earlier.*
PLAGUE

and in 590 a great epidemic at Rome is connected with the pontificate of Gregory the Great. But it spread in face of the
west, as the plague was early reported in towns and radiating inland. In another direction it extended from Egypt along the
north coast of Africa. Whether the numerous pestilences
recorded in the 7th century were the plague cannot now be said;
but it is possible the pestilences in England chronicled by Bele
in the years 664, 672, 670 and 683 may have been of this disease,
especially as in 690 pestis ignovinaria is again reported in Rome.
For the epidemics of the succeeding centuries we must refer to
more detailed works. 1

It is impossible, however, to pass over the great cycle of
epidemics in the 14th century known as the Black Death. Whether in all the pestilences known by that name really were
all referable to the plague is really a subject of doubt, but it is clear that in some at least it was the bubonic plague.
Contemporary observers agree that the disease was introduced from the East; and one eyewitness, Gabriel de
Mussis, an Italian lawyer, traced, or indeed accompanied, the
march of the plague from the Crimea (whether it was said to have
been introduced from Tartary) to Genoa, where with a handful of
survivors of a Genoese expedition he landed probably at the
end of the year 1347. He narrates how the few that had them-
selves escaped the pest transmitted the contagion to all they met. 2 Other accounts, especially old Russian chronicles, place
the origin of the disease in the Steppes of Asia; and Chalayan (or Cathay), which is a name almost confirmed to some extent by Chinese records,
pestilence and destructive inundations are said to have destroyed
the enormous number of thirteen millions. It appears to have
passed by way of Armenia into Asia Minor and thence to Egypt
and northern Africa. Nearly the whole of Europe was gradually
overrun by the pestilence. It reached Sicily in 1346, Constantin-
ople, Greece and parts of Italy early in 1347, and towards the
end of that year Marseilles. In 1348 it attacked Spain, northern
Italy and Rome, eastern Germany, many parts of France
including Paris, and England; from England it is said to have
been conveyed to the Scandinavian countries. In England the
western counties were most severely afflicted early in the year, and
London in November. In 1349 we hear of it in the midlands; and in
subsequent years, at least till 1357, it prevailed in parts of the
country, or generally, especially in the towns. In 1352 Oxford
lost two-thirds of her academical population. The outbreaks of
1361 and 1368, known as the second and third plagues of the
reign of Edward III., were doubtless of the same disease, though
by some historians not called the black death. Scotland and
Ireland, though later affected, did not escape.
The nature of this pestilence has been a matter of much contro-
versy, and some have doubted its being truly the plague. But
when the symptoms are fully described they seem to justify
this conclusion, one character only being thought to make
the distinction between this and Oriental plague, viz. the special
implication of the lungs as shown by spitting of blood and other
symptoms. Guy de Chauliac notes this feature in the earlier
epidemic at Avignon, not in the later. Moreover, as this com-
plification was a marked feature in certain epidemics of plague
in India, the hypothesis has been framed by Hirsch that a special
variety of plague, pestis indica, still found in India, is that which
overran the world in the 14th century. But the same symptoms
(haemoptysis) have been seen, though less notably, in many
places.

1 See Noah Webster's History of Epidemic Diseases, Svo (2 vols., London, 1800) (a work which makes no pretension to medical
learning, but exhibits the history of epidemics in connexion with physical disasters—as earthquakes, famines, &c.); Lersch, Kleine
Post-Chronik (Svo, 1880) (a convenient short compendium, but not always reliable); Cranz, Panepistimia (to A.D. 1650), in Scrutinium pestis (Rome, 1658; Leipzig, 1671, 4to); Bascone, History of Epidemic Pestilences (London, 1851, 8vo).
The most complete medical history of epidemics is Häuser's Geschichte der epidemischen Krankheiten (3rd ed., Jena, 1862),
forming the third volume of his History of Medicine.

2 See the original account reprinted with other documents in Häuser, Geschichte der Mittelalter, trans. by Babington, Sydneyen Soc. (London, 1844); Vollkundliche Gebote des Mittelalters, ed. Hirsch (Berlin, 1865); R. Höeniger, Der schwere Tod in Deutschland (Berlin, 1882).

The Black Death.

In the 15th century the plague recurred frequently in nearly all
countries of Europe. In the first quarter it was very destructive
in Italy, in Spain (especially Barcelona and Seville), in Germany
and in England, where London with severely visited in 1400 and 1406,
and again in 1428. In 1427, 80,000 persons died in Denmark,
and even ravaged the neighbourhood. In 1438-1439 the plague was in
Greece, and its occurrence at Basel was described by Aeneas Sylvius, after-ward Pope Pius II. In 1443, though the plague was severe, but the
Italians were not really severely affected. Hecker calculates that one-fourth of the population of Europe, or 25 millions of persons, died in
the whole of the epidemics.
The mortality of the black death was, as is well known,
immense. It is estimated in various parts of Europe at two-
thirds or three-fourths of the population in the first pestilence,
and even in the second. It is said that during those following
years, 1466, 40,000 persons died of plague in Paris; in
1477-1478 the cities of northern Italy were devastated, and in
1485 Brussels. In the fifteenth year of Henry VII. (1499-1500)
a second great plague visitation was observed in London.
The 16th century was not more free from plague than the 15th.
Simultaneously with a terrible pestilence which is reported to
have been introduced into unpeopled China, plague prevailed over Germany, Holland, Italy and France. It was generally revived at various times in the first half. In 1529 there was plague in
Edinburgh; in London in 1537-1539, and again 1547-1548; and
this year in Paris, though probably not absent before. Some of the epidemics of this period in Italy and Germany are
known by the accounts of eminent physicians, as Vechs, Francastor, Mercurialis, Borgheruci, Ingrosia, Massarini, Amici, &c., whose
writings are important because the question of contagion first began to be raised, and also plague had to be distinguished from
typhus fever, which began in this century to appear in Europe.
The epidemic of 1553-1564 in London and England was
very severe. In 1557 there were plague in London, parts of
London being affected, and the whole of London much
affected. In 1576 plague was an everyday occurrence, of which some were less
afraid than of a headache (Borgheruci). In 1570, 200,000 persons
died in Moscow and the neighbourhood, in 1572, 50,000 at
York; in 1575, 75,000 plague at Edinburgh, and in
London. When, however, in 1575 a new wave of plague passed
over Europe, its origin was referred to Constantinople, whence it was
spread by sea to Malta, Sicily and Italy, and by land through the Austrian territories to Germany. Others considered
that the disease originated locally; and, indeed, considering previous
history, no importation of plague would seem necessary to explain
its presence in Europe. Italy suffered severely (Venice, in 1576, 70,700); North Europe not less, though later; London in
1580-1582. In 1585 Breslau witnessed the most destructive
plague known in its history. The great plague of 1592 in London
seems to have been a part of the same epidemic, which was hardly
extinguished by the end of the century, and is noted in London
again in 1599. On the whole, this century shows a decrease of plague in Europe.

The plague of the first half of the 17th century was still prevalent
in Europe, though considerably less so than in the middle ages.
In the second half a still greater decline is observable, and by the
third quarter the disease had disappeared or was disappearing from a
great part of western Europe. The epidemics in England will be
most conveniently considered in one series. From this time

3 Vechs, Commentarius de peste et pestilence (1537); Francastorius, De Contagione, &c.; D'Alfonso, Opera Omnia, 1540, de Mortalitate, De
peste, praesertim de Veneta et Poloniae (Basel, 1577); Prosper Borgheruci, De peste (Venice, 1565), 8vo; Filippo Ingrasius, In-
formacione del pestifero morbo . . . Palermo e . . . regno di Sicilia (Venice, 1547); Amici, de Peste (Venice, 1597); Dionedes Amici, Tractatus de Peste (Venice, 1599), 4to; Victor de Bonagentibus, Decem probaralata de peste (Venice, 1556), 8vo; Georgius Agricola, De peste libri tres (Basel, 1554), 8vo.
The works of English physicians of this period are of little medical
value; but Lodge's Treatise of the Plague (London, 1603) deserves
mention.
onwards we have the guidance of the "Bills of Mortality" issued in London, which, though drawn up on the evidence of ignorant persons, are doubtless roughly true. The accession of James I. in 1603 marked the very destruction of the first plague which visited London. In this and subsequent years the disease was widely diffused in England—for instance, Oxford, Derbyshire, Newcastle. It prevailed at the same time in Holland, and had done so some years previously in the Low Countries. In the same year (1603) one million persons are said to have died of plague in Egypt. This plague is said to have lasted eight years in London. At events in 1636 we have the second great epidemic, with a death-rate of 11,782. After this there is a remission till about 1620, when plague again began to spread in northern Europe, especially Germany and Holland, and this was at that time ravaged by war. In 1625 (the year that ended in the plague in London) the third great London plague with 35,417 deaths—though the year 1624 was remarkably exempt, and 1626 nearly so. In 1630 was the great plague of Milan, described by Ripamonti. In 1632 a severe epidemic, apparently of the same character as the former ones, raged in the Low Countries. In 1636 is the fourth great plague year in London with a mortality of 10,400, and even in the next year 3082 persons died of the same disease. The same year saw the great inundation of the Ems and the Rhine, with a loss of 95,000.

The Great Plague of London.—The preceding enumeration will have prepared the reader to view the great plague of 1665-1666 in its true relation to others, and not as an isolated phenomenon. The preceding years had been unusually free from plague, and it was not mentioned in the bills of mortality till 1665. The disease spread so rapidly that isolated cases were observed in the parishes of St Giles and St Martin's, Westminster, and a few occurred in the following winter, which was very severe. About May 1665 the disease again became noticeable, and spread, but somewhat slowly. Boghurst, a contemporary doctor, notices that it crept down Holborn and took six months to travel to the western suburbs (St Giles) to the eastern (Stepney) through the city. The mortality rapidly rose from 43 in May to 590 in June, then 637 in July, 17,036 in August, 31,159 in September, after which it began to decline. The total number of deaths from plague in that year, according to the bills of mortality, was 68,506, in a population of about 600,000. But these are not the real figures; there are supposed to have fled to escape the contagion. This number is likely to be rather too low than too high, since of the 6432 deaths from spotted fever many were probably really from plague, though not declared so to avoid painful restrictions. In December there was a sudden fall in the mortality which continued through the winter; but in 1666 nearly 2000 deaths from plague are recorded.

According to some authorities, especially Hedges, the plague was imported into London by bales of merchandise from Holland, which came originally from the Levant; according to others it was introduced by Dutch prisoners of war; but Boghurst regarded it as of local origin. It is in favour of the theory that it spread by some means from Holland that plague had been all but extinct in London for some seventeen years, and prevailed in Holland in 1663-1664. But from its past history and local conditions, London might well be deemed capable of producing such an epidemic. In the bills of mortality since 1663 there are only three years when no deaths from plague are recorded. The uncleanliness of the city was comparable to that of many cities at the present day, and, according to contemporary testimony (Garencières, Anglese flagellum, London, 1647, p. 85), little improved since Erasmus wrote his well-known description. The spread of the disease only partially supported the doctrine of contagion, as Boghurst says: "The disease spread not altogether by contagion at first, nor began only at one place and spread further and further as an eating sore doth all over the body, but fell upon several places of city and suburbs like rain." In fact dissemination seems to have taken place, as usual, by the conversion of one house after another into a focus of infection, by the contagious contact of the sick and healthy, and by the similar custom of shutting up infected houses with all their inmates in Holland, which was almost equivalent to a sentence of death on all therein, but caused a dangerous concentration of the poison. The well-known custom of marking such houses with a red cross and the legend "God have mercy upon us!" was no new thing: it is found in a proclamation in the possession of the present writer dated 1641; and it was probably older still. Hedges testifies to the futility and injurious effects of these regulations. The lord mayor and magistrates not only carried out the appointed administrative measures, but looked to the cleanliness of the city and the relief of the poor, so that there was little or no actual want; and the burial arrangements appear to have been well attended to. The college of physicians, by royal command, put forth such advice and prescriptions as were thought best for the emergency. But it is clear that neither these measures nor medical treatment had any effect in checking the disease. Early in November with colder weather it began to decline; and in December there was so little fear of contagion that those who had left the city "crowded back as thick as they fled." As has often been observed in other plague epidemics, sound people could enter infected houses and even sleep in the beds of those who had died of the plague before they were even cold or cleansed from the stench of the disease (Hedges). The symptoms of the disease were such as have been observed need not be here considered. The disease was, as always, most destructive in squallid, dirty neighbourhoods and among the poor, so as to be called the "poor's plague." Those who lived in the town in bays or ships did not take the disease; and the houses on London Bridge were but little affected. Of those doctors who remained in the city some eight or nine died, not a large proportion. Some had the rare courage to investigate the mysterious disease by dissecting the bodies of the dead. Hedges implies that he did so, though he left no full account of his observations. Dr George Thomson, a chemist and a disciple of Van Helmont, followed the example, and nearly lost his life by an attack which immediately followed this. The plague of 1665 was widely spread over England, and was

1 Josephus Ripamonti, De peste anno 1630 (Milan, 1641), 440.
2 For this period see Index to Memorabiae in Archivis of City of London (1570-1603) (London, 1878); Richardson, Plague and Pestilence in North of England (Newcastle, 1859).
4 On the plague of 1665 see Nath. Hodges, Laiomologia sua pestis superae aetatis populi Londinensi narratio (London, 1672) 8vo—"in English by Quincy (London, 1720), (the chief authority; Aegyptiaca vel miterr-epl or an Experimental Relation of the last Plague in the City of London, by William Boghurst (London, 1668) 4to—A MS. in British Museum (Sloane 349), containing important details; George Thomson, AOMOTOMA, or the Pest Anatomized, 8vo (London, 1666); Sydenham, Tepiys pallialis et pestis annorum 1661-1665, 1665; 8vo—Opera, ed. Greenhill, p. 96 (1644); Collection of Scarcely Pieces on the Plague in 1665 (London, 1721), 8vo; Defoe's fascinating Journal of a Citizen, which should be read and admired as a fiction, but accepted with caution as history; T. Vincent (minister of the gospel), God's Terrible Voice in the City, 8vo (London, 1667); Calendar of State Papers (1665-1666; "Domestic" series), by M. E. Green.
PLAGUE
generally regarded as having been transmitted from London, as it appeared mostly later than in the metropolis, and in many cases the importation by a particular person could be traced. Places near London were most affected, as the French POSITIVE Account (Dana- deFoe) shows; but in June or August 1665 it was already in Southwark on London, &c. A wider distribution occurred in the next year. Oxford entirely escaped, though the residence of the court and the presence of a French ambassador were present during the Nad.
The exemption was attributed to cleanliness and good drainage.

After 1666 there was no epidemic of plague in London or any part of England, though sporadic cases appear in bills of mortality up to 1720, when it finally disappeared. The disappearance of plague in London was attributed to the Great Fire, but no such cause existed in other cities. It has also been ascribed to quarantine, but no effective quarantine was, however, in existence till 1720, so that the cessation of plague in England must be regarded as spontaneous.

But this was no isolated fact. A similar cessation of plague was noticed in Germany and other parts of Western Europe. In 1666 a severe plague raged in Cologne and on the Rhine, which was prolonged till 1720 in the district. In the Netherlands there was a plague in 1666–1667, but there were no definite notices of it after 1667. France saw the last epidemic in 1668, till it reappeared in 1720. In the years 1675–1685 a new epidemic appeared in North Africa, Turkey, Poland, Hungary, Austria and Germany, progressing generally northward. Malta lost 11,000 persons in 1668, and in 1683 it lost 76,000 or probably more deaths. plague in 1661 lost 83,000 by plague. Dresden was affected in 1686, Magdeburg and Halle in 1687, and a mortality of 4,392 persons occurred in the Oktober of about 10,000. Many Northern German cities suffered about the same time; but in 1683 the plague disappeared from Germany till the epidemic of 1707. In Spain it ceased about 1681; in Italy centres at Naples and Venice were attacked till the end of the century, but not later.

**Plague in the 18th Century.**—At the beginning of this period plague was very prevalent in Constantinople and along the Danube. In 1701, for instance, the whole of the city of Prague was attacked, and 60,000 persons died in it. In 1707, plague appeared in Southern Russia and in Poland, and 1744 the disease was in the Ukraine, Hungary, the borders of Carniola, Moravia and Austria, extending along the Carpathians as far as the 60th parallel of North latitude (72° E.). It was not until 1753 that it lasted till 1754, and then disappeared from those parts for fifteen years. In 1755–1757 plague prevailed in parts of European Turkey, whence it on one occasion extended into Transylvania, in the neighbour-

In 1762 a destructive plague arose in Moldavia during the Russo-
Turkish War, and shortly afterwards in Wallachia, apparently endemic in the former country at least. It affected also Trans-
ylvania and part of Hungary, and still more severely Poland, but was confined to Podolia, Volovia, the Ukraine and the east Galicia (5° E.), not even penetrating as far as Warsaw. After destroying, it is said, 300,000 persons, and without being checked by any quarantine regulations, the plague died out finally in March 1771, being remarkable for its short duration and spontaneous limitation.

In another direction the plague spread over Little Russia in 1770, and devastated Kief, while in the next year it broke out in Moscow and produced one of the most destructive epidemics of modern times. More than 50,000 persons, nearly one-fourth of the popula-

The remaining European plague-epidemics of the 18th century were inconsiderable, but on that very account noteworthy. Trans-
ylvania was again affected in 1785, Slavonia and Livonia (a district of eastern Germany), though not far distant, were much affected, with a mortality of 76,000. plague in 1784. The disease, while reappearing in the seats of the terrible earlier epidemics, was more limited in its range and of shorter duration. An epidemic in Dalmatia in 1783–1784 is noteworthy for the rapidity of its development and extent; it affected the Adriatic coast and was quelled in 1784. The 1790s were more peaceful. There were no new, widespread, or serious epidemics. In the last years of the century (1799–1800) there was a new epidemic in Syria and Egypt, where it affected the French and afterwards the English armies.

**Plague in the 19th Century.**—Plague appeared at Constantin-
ople in 1802–1803, about the same time in Armenia (Kars), and in 1804 in Bagdad. It had prevailed since 1798 in Georgia and the Caucasus, and in 1803–1806 began to spread from the north of the Caucasus into Russia, till in 1806 it was established at or near Astrahan, and in 1807 reached Zarreef, 200 m. higher up the Volga. These localities are interesting as being near those where plague appeared in 1827–1878. It is also said to have entered the government of Saratov, but probably no great distance. The plague remained in the Caucasus and Georgia till 1819 at least. In 1828–1838 it was in Armenia, and again in 1840–1843, since which time it has not been heard of in that country.

2. From the annals of the Moravian community of Serepta on the Volga, *Geschichte der Brüder-Gemeinde Serepția*, by A. Güttes (Serepta and Berlin, 1865); also Tholozan, *Épidémies de peste du Caucase* (Paris, 1879).
In 1608 plague was at Constantinople, in 1809 at Smyrna. In 1812 was a more general epidemic affecting these places and also Egypt. An outbreak at Odessa is supposed to have been brought from Constantinople, and thence to have passed to Transylvania. In 1813 a severe plague at Bucharest is supposed to have been brought from Constantinople. About the same time plaque prevailed in Bosnia, and is supposed to have passed thence to Dalmatia in 1815. In 1814-1815 it again appeared in Egypt, and once more invaded the continent of Europe in Albania and Bosnia. Two insular outbreaks, Malta in 1813 and Corfu in 1815, attracted much attention as being both thought to be cases of importation by sea-traffic, and there seems good reason for this opinion.

A panic spread through Europe in 1815 in consequence of an outbreak in Noja on the eastern coast of Italy. According to one view it was imported from the opposite coast of Dalmatia, though no definite history of contagion was established; according to others, it originated endemically in that place. It remained, however, strictly confined to a small district, perhaps in consequence of the extraordinarily rigorous measures of isolation adopted by the Italian government. In 1828 an isolated epidemic appeared in Greece in the Morca, supposed to have been brought by troops from Egypt. In 1824-1825 an outbreak took place at Tutchkoff in Bessarabia; the town was strictly isolated by a military cordon and the disease did not spread. Cronstadt in Transylvania was the scene of a small outbreak in 1828, which was said to be isolated by similar measures (Lorinser). A far more serious epidemic was connected with the campaign of the Russian army against Turkey in 1828-1829. Moldavia, Wallachia and Bessarabia were widely affected; the disease broke out also in Odessa and the Crimea, and isolated cases occurred in Transylvania. The most northerly points reached by the plague were near Czernowitz on the frontier of Bessarabia and Bukowina, and its limitation was as before attributed to the Russian and Austrian military cordon.

In 1831 another epidemic occurred in Constantinople and Roumelia; in 1837 again in Roumelia and in Odessa—its last appearance in these regions, and the last on the European continent except an isolated outbreak in Dalmatia in 1840, and one in Constantinople in 1841.

The plague-epidemics in Egypt between 1833 and 1845 are very important in the history of plague, since the disease was almost for the first time scientifically studied in its home by skilled European physicians, chiefly French. The disease was found to be less contagious than reported earlier by the French tradition, and most of the French school went so far as to deny the contagiousness of the disease altogether. The epidemic of 1834-1835 was not less destructive than many of those notorious in history; but in 1842-1845 the disease disappeared.

In 1853 plague appeared in a district of western Arabia, the Asir country in North Yemen, and it is known to have occurred in the same district in 1815, as it did afterwards in 1874 and 1879. In 1874 the disease extended within four days' march of Mecca. From the scantiness of population the mortality was not great, but it became clear that this is one of the endemic seats of plague.

In June 1867 intelligence was received in Constantinople of an outbreak of disease at the small town Benghisi, in the district of Barca, province of Tripoli, North Africa, which though at first misunderstood was clearly bubonic plague. From later researches there is reason to believe that it began in 1856 or in 1855. The disease did not spread, and ceased in the autumn, to

return with less violence in 1859, when it died out. In the autumn of 1873 it returned, but came again to a spontaneous termination.

After the epidemic of Benghisi in 1856-1859, plague was next heard of in the district of Muk, in the extreme north-west of Persia in November 1863. It occurred in a scattered population, and the mortality was not absolutely large.

In 1867 an outbreak of plague was reported in Mesopotamia (Iraq), among the marshes of Hindieh bordering on the lower Euphrates. The epidemic began in December 1866 (or probably earlier) and ceased in June 1867. But numerous cases of non-fatal mild bubonic disease (mild plague or pestis minor) occurred both before and after the epidemic, and according to Tholozan similar cases had been observed nearly every year from 1856 to 1865.

The next severe epidemic of plague in Iraq began in December 1873. But facts collected by Tholozan show that pestis minor, or sporadic cases of true plague, had appeared in 1868 and subsequent years. The outbreak of 1873-1874 began about 60 m. from the origin of that of 1867. It caused a much greater mortality and extended over a much wider area than that of 1867, including the towns of Kerbela and Hilleh. After a short pause, the epidemic reappeared at Divanieh in December 1874, and spread over a much wider area than in the previous epidemics. This epidemic was carefully studied by Surgeon-Major Colvill. He estimated the mortality at 4000. The epidemic ceased in July, but broke out again early in 1876, and in this year extended northwards to Bagdad and beyond. The whole area now affected extended 250 m. from north-west to south-east, and the total number of deaths was believed to be 20,000. In 1877 plague also occurred at Shuster in south-west Persia, probably conveyed by pilgrims returning from Iraq, and caused great mortality.

After its customary cessation in the autumn the epidemic began again in October 1876, though sporadic cases occurred all the summer. The disease appeared in 1877 in other parts of Mesopotamia also with less severity than in 1876, but over a wider area, being now announced at Samara, a town 70 m. above Bagdad on the Tigris. The existence of plague in Bagdad or Mesopotamia was not again announced till the year 1884, when accounts again appeared in the newspapers, and in that July the usual official statement was made that the plague had been stamped out.

In 1879-1871 it appeared in a district of Mukri in Persian Kurdistan to the south of Lake Jrumiah (late removed from the province of Hamadan). The epidemic appears, however, to have died out in 1871, and no further accounts of plague there were received. The district had suffered in the great epidemic of plague in Persia in 1829-1835. In the winter 1876-1877 a disease which appears to have been plague appeared in two villages in the extreme north of the province of Khortas, about 25 leagues from the south-east angle of the Caspian Sea. In March 1877 plague broke out in Resit, a town of 20,000 inhabitants, in the province of Ghilan, near the Caspian Sea at its south-west angle, from which there is a certain amount of trade with Astrakhan. In 1852 a very destructive plague had carried off half the inhabitants. In 1877 the plague was very fatal. From March to September 4000 persons were calculated to have died. The disease continued till the spring of 1878. In 1879 there was a doubtful report of the same disease at Astrabad, and also in some parts near the Perso-Afghan frontier. In 1878 plague again occurred in Kurdistan in the district of So-uj-Bulak, said by Dr. Tholozan to be the same as in the district of Mukri where it occurred in 1879-1871. These scattered outbreaks of plague in Persian territory are the more remarkable because that country
had been generally noted for its freedom from plague (as compared with Asiatic Turkey and the Levant).

A few cases of plague occurred in January 1877 at Baku on the west shore of the Caspian, in Russian territory.1

An outbreak of plague on European soil in 1878–1879 on the banks of the Volga caused a panic throughout Europe.2 In the summer of 1877 a disease prevailed in several villages in the neighbourhood of Astrakhan and in the city itself, which was clearly a mild form of plague (*pestis minor*). It caused no deaths (or only one due to a complication) and died out apparently spontaneously. An official physician, Dr Kastorsky, who investigated the matter for the government, declared the disease to be identical with that prevailing in the same year at Resht in Persia; another physician, Dr Janzky, even gave it the name of *pestis nostras*. In October 1878 some cases appeared in the stanitsa or Cossack military settlement of Vetlanka, 130 m. from Astrakhan on the right bank of the Volga, which seem to have puzzled the physicians who first observed them, but on the 30th of November were recognized as being but the same mild plague as had been observed the year before near Astrakhan by Dr Döppner, chief medical officer of the Cossacks of Astrakhan. His report on the epidemic is the only original one we have. At the end of November the disease became suddenly more severe, and most of those attacked died; and from the 21st of December it became still more malignant, death occurring in some cases in a few hours, and without any buboes being formed. No case of recovery was known in this period. At the end of the year it rapidly declined, and in the first weeks of January still more so. The last death was on the 24th of January. In the second half of December, when the disease had already lasted two months, cases of plague occurred in several neighbouring villages, all of an extremely malignant type, so that in some places all who were attacked died. In most of these cases the disease began with persons who had been at Vetlanka, though this was not universally established. The inhabitants of these villages, terrified at the accounts from Vetlanka, strictly isolated the sick, and thus probably checked the spread of the disease. But it evidently suffered a spontaneous decline. By the end of January there were no cases left in the district except at one village (Selitreynoye), where the last occurred on the 9th of February. The total number of cases in Vetlanka, out of a population of about 1700, was 417, of whom 362 died. In the other villages there were about 62 deaths from plague, and not more than two or three cases of recovery. In consequence of the alarm excited by this appearance of plague upon European soil, spontaneous governments sent special commissions to the spot. The British commissioners were Surgeon-Major Colvill and Dr J. F. Payne, who, like all the foreign commissioners, reached the spot when the epidemic was over. With respect to the origin of this epidemic, the possibility of its having originated on the spot, as in Resht and on the Euphrates in very similar situations, is not to be denied. An attempt was made to show that the contagion was brought home by Cossacks returning from the Turkish War, but on absolutely no evidence. In the opinion of Dr Payne the real beginning of the disease was in the year 1877, in the vicinity of Astrakhan, and the sudden death of the man from Vetlanka on the 30th of November was no more than had been observed in other places. The Astrakhan disease may have been imported from Resht or Baku, or may have been caused concurrently with the epidemics of these places by some cause affecting the basin of the Caspian generally.

**Plague in India.**—It used to be held as a maxim that plague never appeared east of the Indus; nevertheless it was observed during the 19th century in more than one distinct centre in India. So long ago as 1815 the disease appeared in Gugarat, Kattwyar and Cutch, "after three years of severe famine."

3 The dates are all reduced to new style.

6 Manson in *Reports of Imperial Chinese Customs*, special series No. 2, for half-year ended the 31st of March 1878, 15th issue (Shanghai); Lowry, *Notes on Epidemic Disease at Pekin* (1882), *ibid.*, 24th issue, p. 31.
to be freed from its presence, namely, England, Portugal and Spain. From all these it finally disappeared about 1680, at the close of a period of pandemic prevalence. Northern and central Europe became free about 1714, and the south of France in 1722. The last outbreak in northern Russia occurred in 1770. After this plague only appeared in the south-east of Europe, where it rapidly died out during the first half of the 19th century. In 1841 its long reign on this continent came to an end with an isolated outbreak in Turkey. From that time until quite recently it remained extinct, except in the East. The province of Astrakhan, where a very small and limited outbreak occurred in 1878, is politically in Europe, but geographically it belongs rather to Asia. And even in the East plague was confined to more or less clearly localized epidemics; it showed no power of pandemic diffusion. In short, if we regard the history of this disease as a whole, it appears to have lost such power from the time of the Great Plague of London in 1665, which was part of a pandemic wave, until the present day. This was not merely a gradual withdrawal eastwards lasting nearly two hundred years, but the outbreaks which occurred during that period, violent as some of them were, showed a constantly diminishing power of diffusion and an increasing tendency to localization. The sudden reversal of that long process is therefore a very remarkable occurrence. Emerging from the remote endemic centres to which it had retreated, plague has once more taken its place among the zymotic diseases with which Western communities have to reckon, and that which has for more than a century been little more than a name and a tradition has become the familiar object of investigation, carried on with all the ardour and all the resources of modern science. In what follows an attempt will be made to summarize the facts and indicate the conclusions to be drawn from recent experience.

**Diffusion.**—At the outset it is characteristic of this subtle disorder that the present pandemic diffusion cannot be traced with certainty to a definite time or place of origin. Herein it differs notably from other exotic diseases liable to similar diffusion. For instance, the last visitation of cholera could be traced clearly and definitely to a point of origin in northern India in the spring of 1862, and could be followed thence step by step in its march westward (see Cholera). Similarly, though not with equal precision, the last wave of influenza was traced clearly and definitely to central Asia in the spring of 1889, to have travelled through Europe from east to west, to have been carried thence across the sea to America and the Antipodes, until it eventually invaded every inhabited part of the globe (see Influenza). In both cases no doubt remains that the all-important means of dissemination is human intercourse. The movements of plague cannot be followed in the same way. With regard to origin, several endemic centres are now recognized in Asia and Africa, namely, (1) the district of Assy in Arabia, on the eastern shore of the Red Sea; (2) parts of Mesoopotamia and Persia; (3) the district of Garwhal and Kumaon in the North-West Provinces of India; (4) Yunnan in China; (5) East and Central Africa. The last was discovered by Dr. Koch. It includes the district of Kisba in German East Africa, and extends into Uganda. In applying the term "endemic centres" to these localities, no very precise meaning can be attached to the word. They are for the most part so remote, and the information about them so scanty, that our knowledge is largely guesswork. What we mean is that there is evidence to show that under various names a disease identical with plague has been more or less continuously prevalent for a number of years, but how long and how continuously is not known. Whether any of them are permanent homes of plague the evidence does not enable us to say. They seem, at any rate, to have harboured it since its disappearance from Europe, and further investigation would disclose a still wider prevalence. For instance, there are good reasons for believing that the island of Réunion has been subject, since 1840 or thereabouts, to outbreaks under the name of "lymphangite infectieuse," an elegant euphemism characteristically French. In all the countries named plague appears to behave very much as it used to do in Europe from the time of the Black Death onwards. That is to say, there are periods of quiescence, with epidemic outbreaks which attract notice at irregular intervals.

Taking up the story at the point where the earlier historical summary leaves off, we get the following list of countries in which plague is known to have been present in each year (see Local Government Board's Reports): 1880, Mesopotamia; 1881, Mesopotamia, Persia and China; 1882, Persia and China; 1883, China; 1884, China and India (as mokharni); 1885, Persia; 1886, 1887, 1888, India (as mokharni); 1889, Arabia, Persia and China; 1890, Arabia, Persia and China; 1891, Arabia, China and India (as mokharni); 1892, Mesopotamia, Persia, China, Russia (in central Asia); 1893, Arabia, China, Russia and India (as mokharni); 1894, Arabia, China and India (as mokharni); 1895, Arabia and China; 1896, Arabia, Asia Minor, China, Japan, Russia and India (Bombay); 1897, Arabia, China, Japan, India, Russia and East Africa; 1898, Arabia, Persia, China, Japan, Russia, East Africa, Madagascar and Vienna; 1899, Arabia, Persia, China, Japan, Mesopotamia, East Africa, West Africa, Philippine Islands, Straits Settlements, Madagascar, Mauritius, Réunion, Egypt, European Russia, Portugal, Sandwich Islands, New Caledonia, Paraguay, Argentine, Brazil; 1900, to the foregoing should be added Turkey, Australis, California, Mexico and Glasgow; in 1901, South Africa and in 1902 Russia chiefly at Odessa.

This list is probably by no means exhaustive, but it sufficiently indicates in a summary fashion the extent of that wave of diffusion which set in during the closing years of the 19th century. It did not fully gather way till 1896, when plague appeared in Bombay, but our modern knowledge of the disease dates from 1894, when it attacked Hong Kong and first presented itself to accurate observation. From this point a more detailed account may be given. Plague was recognized at Hong Kong in May 1894, and there can be little doubt that it was imported from Canton, where a violent outbreak—said to have caused 100,000 deaths—was in progress a few months earlier, being part of an extensive wave of infection which is believed to have come originally out of the province of Yunnan, one of the recognized endemic centres, and to have invaded a large number of places in that part of China, including Pakholi and other seaports. Hong Kong was severely affected, and has never since been entirely free from plague. In two intermediate years—1895 and 1897—very few cases were recorded, but more recently the epidemic has gathered force again. The following table gives the cases and deaths in each of the six years 1894-1899:

The excessively high rate of mortality is probably due in part to under-statement of the number of cases. Concealment is practised by the Chinese, who are chiefly attacked, and it is easier to conceal sickness than death. Plague appears to have been equally persistent and destructive on the mainland in southern China during the period indicated, but no accurate details are available. In 1897 the Portuguese settlers in addition to the provinces of Yunnan, Kwang-si and Kwang-tung in southern China, plague is reported to have been present for several years in a district in Mongolia to the north of Peking, and distant about "twelve days' ride." More recently several localities in Mongolia and Manchuria have been affected. Formosa was attacked in 1896, and suffered considerably in subsequent years; in 1899 the Japanese government officially reported 2643 cases, with
1794 deaths. Japan itself has had a certain amount of imported plague, but not on a large scale. Speaking generally, the disease has persisted and spread in the Far East since 1864, but precise information is lacking, except with regard to Hong Kong. W. J. Simpson in his Report on the Causes of the Plague in Hong Kong (1903) reports the endemism of the plague in that colony to be maintained by (a) infection among rats often connected with infectious material in rat runs or in houses, the virus of which has not been destroyed, (b) retention of infection in houses in which are rat-ridden, and (c) infected clothing of people who have been ill or died of plague. He considers the outbreaks are favoured by the seasonal heat and moisture of the spring and early summer, and the movement from place to place of infected rats or persons. He also believes that human beings may infect rats. In 310 cases of plague examined by Simpson 56% were bubonic, 40% septic and 4% pneumonic.

In 1896 plague appeared in the city of Bombay. It was certainly present in August, but was not recognized until the 23rd of September, and the diagnosis was not bacteriologically confirmed until the 13th of October. This fact should be remembered when failure to recognize the disease on its first appearance occurs elsewhere. The origin of the Bombay invasion is shrouded in obscurity. It is not even known when, or in what part of the city it began (Condon, The Bombay Plague). Several theories have been put forward, and importation by sea from China is the theory which has met with most acceptance. The native form of plague, known as mahamari, is confined to the southern slopes of the Himalaya. It is described above, but that account may be supplemented by some earlier references unearthed by the Bombay Gazetteer (vol. iv.). Ibn Batuta notices two destructive pestilences in the 14th century, and Ferishta one in 1443, which he calls ta’um, and describes as very unusual in India. At the end of the 16th century there was a pestilence following a prolonged famine, and in the 17th century two violent epidemics are recorded under the names ta’um and waba. In the second of these, which occurred in the Ahmedabad district of the Bombay Presidency in 1683–89, buboes are distinctly described. In the 18th century several pestilences are recorded without description. It is at least probable from these notes that even before the undoubted outbreak, which began in Cutch in 1812, India was no stranger to epidemic plague. To return to Bombay and 1896: the infection spread gradually and slowly at first, but during the first three months of 1897 not only was the town of Bombay severely affected, but district after district in the presidency was attacked, notably Poona, Karachi, Cutch Mandvi, Bhivandi and Daman. The number of cases and deaths reported in the presidency, exclusive of the city, in each year down to the end of 1899, was as follows:

<table>

The total for the presidency, including the city, in four years was 325,632 cases with 252,549 deaths in a population of 26,660,421 (census of 1891). The population of the city is 821,764, but during the earlier plague period large numbers fled, so that the foregoing figures do not give the true plague incidence according to population. Moreover, concealment was extensively practised. The most striking fact brought out by the tables just given is the large and steady increase year by year in the presidency, in spite of all efforts to arrest the spread of infection. It has gone on since 1890, and it has not been confined to Bombay, but has extended over the whole of India. In 1897 it had already penetrated to Rajputana, the Punjab, the North West Provinces and the Central Provinces. In the following year Bengal, Madras, Haidarabad and Mysore were invaded. Not all these provinces suffered alike, but on the whole plague steadily strengthened its hold on India generally, and hardly relaxed it in any part. The most noteworthy details available are as follows, taken from the plague mortality returns published June 1906. In the Bombay from 179 deaths in 1897 the mortality reached a maximum of 334,897 in 1905, in Agra and Oudh they rose from 72 in 1897 to 383,802 in 1905, and in Madras Presidency from 1658 in 1899 to 20,125 in 1904.

The most striking figures, however, are those for Bombay and Bengal which are given below, as well as the total mortality in India.

</table>

Outside China and India plague has caused no great mortality in any of the countries in which it has appeared, with the exception perhaps of Arabia, about which very little is known. But some of the outbreaks are interesting for other reasons, and require notice. The first case is the singular occurrence of three deaths at Vienna in October 1898. The earliest victim was an attendant named Barisch, employed in the pathological laboratory of the Vienna General Hospital, and told off to look after the animals and bacteriological apparatus devoted to the investigation of plague, cultures of which had been brought from India by the medical commissioners sent by the Royal Academy of Science in 1897. Barisch was drunk and out all night on the 8th of October; on the 14th of October he fell ill. Plague was suspected, but Dr Müller, who attended the man and had studied the disease in India, would not admit the diagnosis on clinical grounds, nor was it bacteriologically established until the 19th of October. Barisch died on the 18th of October. On the 20th one of the nurses, and on the 21st Dr Müller, fell ill. Both died of pneumatic plague, from which also Barisch had unnecessarily suffered. A second nurse and a sister of mercy had feverish attacks, but no further case occurred. Barisch was shown to have been careless in the performance of his duties, and to have disregarded instructions; and the inference is that he conveyed the infection to his mouth, and so to the lungs, from the bacteriological specimens or inoculated animals. The melancholy incident illustrates several points of interest: (1) the correctness of the bacterial theory of causation, and the identity of the bacillus pestis as the cause; (2) the infectious character of the pneumatic type of disease; (3) its high fatality; (4) the difficulty of diagnosis.

The next occurrence of special interest is the appearance of plague in Portugal in 1899, after an absence of more than 200 years. Its origin is shrouded in obscurity. Oporto, the seat of the outbreak, had no connexion by sea with any place known to be infected, and all attempts to trace introduction ended in speculation or assumption. The most probable theory was that soldiers returning home from infected Portuguese possessions in the East brought it with them, but this does not explain the selection of Oporto and the escape of other places. The earliest
cases, according to retrospective inquiry, occurred in June 1899; suspicions were aroused in July, but the diagnosis was not established until August. The conclusion reached, after careful investigation by Dr Jorge, the medical officer of health, that the commencement really dated from June, is confirmed by the fact that about that time the river users, who had been affected, began to notice an illness among themselves sufficiently novel to attract their attention and that of an English shipowner, who from their description suspected plague. Through him the suspicion was conveyed to the Medical Times and Gazette, in which the suggestion of plague at Oporto was made before any public mention of it in the town itself. The outbreak never assumed large proportions. It gained ground by degrees until October, after which it declined, and eventually ceased in February 1900. No recrudescence has been officially announced. The number of cases recorded in a population of 130,000 was 310, with 114 deaths, representing a case mortality of 36.7%. They were widely scattered about the town and outlying suburbs; but no further extension occurred, except some isolated cases at Braga, a town 35 m. distant, and one at Lisbon, in the person of the distinguished bacteriologist, Professor Camara Pestana, who contracted the disease in making a post-mortem at Oporto, and died in Lisbon.

The only other appearance of plague in Europe in 1899 was on the Volga. Three places were affected, namely, Kolobovka, and Krasnoyarsk, in the province of Astrakhan, and Samara, higher up the river. All three outbreaks were small and limited, and no further extension took place. A commission appointed by the Russian Government pronounced the disease to be undoubtedly plague, and it appears to have been very fatal. The origin was not ascertained.

The most interesting extensions of plague in 1900 were those in Australia and Glasgow. The following towns were affected in Australia: Sydney, in New South Wales; Adelaide, in South Australia; Melbourne, in Victoria; Brisbane, Rockhampton, Townsville, Cairns and Ipswich, in Queensland; Fremantle, Perth and Coolgardie, in West Australia. In none of these, with the exception of Sydney, did plague obtain a serious hold. The total number of cases reported in Queensland was only 123, with 53 deaths. In Sydney there were 363 cases, with 103 deaths, a case mortality of 34%. The infection is supposed to have been brought from Noumea, in New Caledonia, where it was present at the end of 1899; and the medical authorities believe that the first case, which occurred on the 9th of January, was recognized. The outbreak, which hardly reached epidemic proportions, lasted about six months. That in Glasgow was on a still smaller scale. It began, so far as could be ascertained, in August 1900, and during the two months it lasted there were 34 cases and 15 deaths. Once more the disease was not at first recognized, and its origin could not be traced. In 1901 plague invaded South Africa, and obtained a distinct footing both at Cape Town and Port Elizabeth. The total number of cases down to July was 760, with 362 deaths; the number of Europeans attacked was 196, with 68 deaths, the rest being natives, Malays, Indians, Chinese and negroes. With regard to Great Britain, a few ship-borne cases have been dealt with at different ports from time to time since 1896, but except at Glasgow the disease has nowhere obtained a footing on land.

Causation.—Plague is a specific infectious fever, caused by the bacillus pestis, which was identified in 1894 by Kitasato, and subsequently, but independently, by Yersin (see Parasitic Diseases). It is found in the buboes in ordinary cases, in the blood in the so-called "septicæmic" cases, and in the sputum of pneumonic cases. It may also be present in the urine. Post mortem it is found in great abundance in the spleen and liver. Nothing is known of its natural history outside the body, but on culture it is apt to produce numerous involution forms. Its presence in a patient is regarded as positive diagnostic proof of plague; but failure to find or to identify it does not possess an equal negative value, and should not be too readily accepted, for many instances are recorded in which expert observers have only succeeded in demonstrating its presence after repeated attempts. It is clear, from the extreme variations in the severity of the illness, that the resisting power of individuals varies greatly. According to the Plague Research Committee of Bombay, the predisposing causes are "those leading to a lower state of vitality," of which insufficient food is probably the most important. There is no evidence that age, sex or race exercises a distinct predisposing influence. The largest incidence in Bombay was on young adults; but then they are more numerous and more exposed to infection, because they go about more than the younger and the older. Similarly, the comparative immunity of Europeans in the East may be explained by their different conditions of life. It is doubtful whether the distinction drawn between pestis minor and pestis major has a real aetiological basis. Very mild cases occurring in the course of an outbreak of typical plague may be explained by greater power of resistance in individuals, but the epidemic prevalence of a mild illness preceding the appearance of undoubted plague suggests some difference or modification of the exciting cause.

"It is impossible," writes Sir Richard Thorne (Local Government Board Report, 1898-1899), "to read the medical history of this disease in almost every part of the world without being impressed with the frequency with which recognized plague has been preceded by ailments of such slight severity, involving some bubonic enlargement of glands and some rise in body-temperature, as to mask the real nature of the malady." Considering the great importance of arresting the spread of infection at the outset, and the implicit reliance placed upon bacteriological criteria, the aetiology of such antecedent ailments deserves more attention than has hitherto been paid to it. Of course plague does not stand alone in this respect. Epidemic outbreaks of other diseases—for instance, cholera, diphtheria and typhoid fever—are often preceded and followed by the prevalence of mild illness of an allied type; and the true significance of this fact is one of the most important problems in epidemiology. In plague, however, it is of special importance, on account of the peculiarly insidious manner in which this disease fastens itself upon a locality.

The path by which the bacillus enters the body varies. In pneumonic cases it is presumed to enter by the air-passages, and in bubonic cases by the skin. The Bombay Plague Research Committee, whose experience is unparalleled, say: In a number of instances points of inoculation were found on the extremities of patients, from which plague cultures were obtained, and in these cases buboes were found above the point of inoculation. In the majority of instances, however, no local indication could be found marking the point at which the microbe was implanted." From the fact that bacilli are hardly ever found in the blood of bubonic cases it may be inferred that they are arrested by the lymphatic glands next above the seat of inoculation, and that the fight—which is the illness—takes place largely in the bubo; in non-bubonic cases they are not so arrested, and the fight takes place in the general circulatory system, or in the lungs. As might be expected from these considerations, the bubonic type is very little infectious, while pneumonic cases are highly so, the patients no doubt carrying the surrounding atmosphere by coughing. Whether infection can be introduced through the digestive tract by infected food is doubtful. The bacillus is non-resistant and easily killed by heat and germicide substances, particularly acids. Little is known of its toxic action; only a weak toxin has been obtained from cultures. Of the lower animals, mice, rats, guinea-pigs, rabbits, squirrels and monkeys are susceptible to the bacillus; horses, cattle, sheep, goats, pigs, dogs and cats are more or less resistant, but cats and dogs have been known to die of plague (Oporto, Daman, Cutch and Patiala). Great Plague of the East, however, could carry the infection, and were killed in vast numbers.

The bacillus has been demonstrated in the bodies of fleas, flies, bugs and ants.

Clinical Characters.—One of the results of recent observation is the classification of plague cases under three heads, which have already been mentioned several times: (1) bubonic, (2) pneumonic, (3) septicæmic. (The word "pesti-caemic" is
also used instead of "septi-caemic," and though etymologically objectionable, it is otherwise better, as "septicemia" already has a specific and quite different meaning.) It should be understood that this classification is a clinical one, and that the second and third varieties are just as much plague as the first. In bubonic plague, because of frequent use of the word "bubonic" has given rise to the erroneous idea that true plague is necessarily bubonic, and that non-bubonic types are a different disease altogether. The word "plague"—or "pest," which is the name used in other languages—had originally a general meaning, and may have required qualifications when applied to this particular fever; but it has now become a specific label, and the prefix "bubonic" should be dropped.

The illness varies within the widest limits, and exhibits all gradations of severity, from a mere indisposition, which may pass almost unnoticed, to an extreme violence, only equalled by the most violent forms of cholera. The mild cases are always bubonic; the other varieties are invariably severe, and almost always fatal. Incubation is generally from four to six days, but it has been observed as short as thirty-six hours and as long as ten days (Bombay Research Committee). Incubation, however, is so difficult a thing to determine that it is unwise to lay down any positive limit. As a rule the onset is sudden and well marked. The symptoms may be described under the headings given above. (1) Bubonic cases usually constitute three-fourths of the whole, and the symptoms may therefore be called typical. In a well-marked case there is usually an initial rigor—in children convulsions—followed by a rise of temperature, with vomiting, headache, giddiness, intolerance to light; pain in epigastrium, back and limbs; sleeplessness, apathy or delirium. The headache is described as splitting; delirium is of the busy type, like delirium tremens. The temperature varies greatly; it is not usually high on the first day—from 101° to 103°—and may even be normal, but sometimes it rises rapidly to 104° or 105° or even 107° F.; a full of two or three degrees on the second or third day has frequently been observed. The eyes are red and injected; the tongue is somewhat swollen, and at first covered with a thin white fur, except at the tip and edges, but later it is dry, and the fur yellow or brownish. Prostration is marked. Constipation is the rule at first, but diarrhoea may be present, and is a bad sign. A characteristic symptom in severe cases is that the patient appears dazed and stupid, is thick in speech, and staggers. The condition has often been mistaken for intoxication. There is nothing, however, in all these symptoms positively distinctive of plague, unless it is already prevalent. The really pathognomonic sign is the appearance of buboes or inflamed glands, which happens early in the illness, usually on the second day; sometimes they are present from the outset, sometimes they cannot be detected before the third day, or even later. The commonest seat is the groin, and next to that the axilla; the cervical, submaxillary and femoral glands are less frequently affected. Sometimes the buboes are multiple and on both sides, but more commonly they are unilateral. The pain is described as lancinating. If left, they usually suppurate and open outwards by sloughing of the skin, but they may subside spontaneously, or remain hard and indurated. Petechiae occur over buboes or on the abdomen, but they are not very common, except in fatal cases, when they appear shortly before death. Boils and carbuncles are rare. (2) Pneumonic plague was observed and described in many of the old epidemics, and particularly by two medical men, Dr Gilder and Dr Whyte, in the outbreak in Kathiawar in 1816; but its precise significance was first recognized by Childe in Bombay. He demonstrated the presence of the bacillus in the sputum and in the blood, and the inflammation of the lungs as a set of lesions primary plague infection. The pneumonic is usually lobular, the onset marked by rigors, with difficult and hurried breathing, cough and expectoration. The prostration is great and the course of the illness rapid. The breathing becomes very hurried—forty to sixty respirations in the minute—and the face dusky. The expectoration soon becomes watery and profuse, with little whitish specks, which contain great quantities of bacilli. The temperature is high and irregular. The physical signs are those of broncho-pneumonia; oedema of the lungs soon supervenes, and death occurs in three or four days. (3) In septicaemic cases the symptoms are those of the bubonic type, but more severe and without buboes. Prostration and cerebral symptoms are particularly marked; the temperature rises rapidly and very high. The patient may die comatose within twenty-four hours, but more commonly death occurs on the second or third day. Recovery is very rare.

There is no reason for doubting that the disease described above is identical with the European plagues of the 14th and subsequent centuries. It does not differ from them in its clinical features more than epidemics of other diseases are apt to vary at different times, or more than can be accounted for by difference of handling. The swellings and discolorations of the skin which play so large a part in old descriptions would probably be equally striking now but for the surgical treatment of buboes. Similarly, the comparatively small destructiveness of modern plague, even in India, may be explained by the improved sanitary conditions and energetic measures dictated by modern knowledge. The case mortality still remains exceedingly high. The lowest recorded is 34% in Sydney, and the highest 95% at Hong Kong in 1899. During the first few weeks in Bombay it was calculated by Dr Viegas to be as high as 99%. It is very much higher among Orientals than among Europeans. In the Bombay hospitals it was about 70% among the former, and between 30 and 40% among the latter, which was much the same as in Oporto, Sydney and Cape Town. It appears, therefore, that plague is less fatal to Europeans than cholera.

The average duration of fatal cases is five or six days; in the House of Correction at Byculla, where the exact period could be well observed, it was five and a half days. Patients who survive the tenth or twelfth day have a good chance of recovery. Convalescence is usually prolonged. Second attacks are rare, but have been known to occur.

Diagnosis.—When plague is prevalent in a locality, the diagnosis is easy in fairly well-marked cases of the bubonic type, but less so in the other varieties. When it is not prevalent the diagnosis is never easy, and in pneumonic and septicaemic cases it is impossible without bacteriological assistance. The earliest cases have hardly ever been even suspected at the time in any outbreak in a fresh locality. It may be taken at first for almost any fever, particularly typhoid, or for venereal disease or lymphangitis. In plague countries the diseases with which it is most liable to be confounded are malaria, relapsing fever and typhus, or broncho-pneumonia in pneumonic cases.

Treatment.—The treatment of plague is still symptomatic. The points requiring most attention are the cerebral symptoms—headache, sleeplessness, delirium, &c.—and the state of the heart. Alcohol and cardiac stimulants may be required to prevent heart failure. Speaking generally, it is important to preserve strength and guard against collapse. Extracts of suprarenal gland have been found useful. Buboes should be treated on ordinary surgical principles. An antitoxic serum has been prepared from horses by the Institut Pasteur in France, but has not met with success. The results in India obtained by British and various foreign observers were uniformly unfavourable, and the verdict of the Research Committee (1900) was that the serum had "failed to influence favourably the mortality among those attacked." Success was somewhat noisily claimed for an improved method tried in Oporto, but the evidence is of little or no value. Of 142 cases treated, 21 died; while of 72 cases not treated, 46 died; but the former were all hospital patients, and included several convalescents and many cases of extreme mildness, whereas the non-serum cases were treated at home or on the road, and the sera probably not discovered until death had made further concealment impossible. Later observations have, however, established that the Yersin-Roux serum is of undoubted benefit when used early in the case, in fact during the first twenty-four hours. Very large doses, so much as 150 cc. may be injected subcutaneously or preferably intravenously, and it is stated to modify the whole course of
the disease. Another serum has been prepared by Lustig and Galeotti.

**Morbid Anatomy.**—(1) Bubonic cases. A bubo is found to consist of a chain of enlarged glands, surrounded by a mass of engorged connective tissue, coagulated blood and serum. Nearly all the lymphatic glands in the body are a little swollen, but this swelling is not so marked in the hemenymphatic glands. The spleen and liver are always enlarged, the former to sometimes twice its natural size. The lungs are engorged and oedematous, and often show haemorrhages. The kidneys are enlarged and congested. The serous membranes show petechiae and haemorrhages. The right side of the heart is frequently dilated, with clots in the cavities. The heart muscle is normal, or soft and friable. The substance of the brain, spinal cord and nerveroots is normal, but the membranes are engorged. (2) Pneumonic cases. The lymphatic glands are hardly affected. There is general engorgement and oedema of the lungs, with pneumatic patches varying in size and irregularly distributed. (3) Septicaemic cases. Nearly all the lymphatic glands in the body are involved, and have a characteristic appearance. They are enlarged to the size of an almond, rounded, firm and pink; there is some engorgement and oedema on section; the substance is rather soft, and can be scraped off with a knife. The surrounding tissue is not engorged or oedematous. The description of the other organs given under (1) applies also to (2) and (3).

**Dissemination.**—Given the bacillus, the questions arise, How is it disseminated? and What are the conditions that favour its propagation? That it is conveyed from person to person is an undoubted fact, proved by innumerable cases, and tacitly implied by the word "infectious," which is universally allowed. The sick are a source of danger and one means of dissemination, and, since the illness may be so slight as to pass unrecognized, an obviously insidious one. The ambulatory plague patient goes far to explain the spread of the disease without leaving any track. But there is evidence that persons may carry the infection and give it to others without being ill at all themselves. One such case occurred at Glasgow, and another at Oporto. In the Glasgow case the wife of a laundryman employed in handling plague linen contracted the disease. She was brought into connexion with it in no other way, and there can be no doubt that she took it from her husband, though he was not ill at all himself. The Oporto instance is still more conclusive. Two little girls had plague at Argonville, a suburb some miles from Oporto, and were the only cases which occurred in that place. Their father was a riverside labourer, who lodged during the week in Oporto, but went home for Sunday. He was not ill, but several cases of plague occurred in the house in which he lodged. How the poison passes from one person to another is less clear. In pneumatic cases patients no doubt spread it around them by coughing, and others may take it up through the air-passages or the skin; but even then the range of infection is small, and such cases are comparatively rare. In the vast majority of cases the bacillifer are in the lymphatic or the circulatory system, and aerial infection, even for a short distance, seems highly improbable. This view is borne out by the experience in hospitals and with "contacts," which goes to show that with reasonable care and under fair conditions the risk of infection from ordinary plague patients is very small. When persons live crowded together in close contact, and when they are careless with regard to discharges of all kinds from patients, the risk is obviously much increased. Discharges—vomited matters, spuia, urine and faeces—are possible media by which plague is spread from person to person. They also contaminate clothing, which thus becomes another means of dissemination capable of acting at a distance. This is the most probable explanation of the two cases of indirect infection related above. From the lymphatic vessels the bacillus has been borne by plague patients proves nothing. Such clothing is not necessarily infectious; indeed, the probability is that it is not, unless contaminated by discharges. There is no evidence that merchandise and food-stuffs are means of dissemination, but a great deal of evidence against such a theory. Then we come to the lower animals. Attention has been concentrated on rats, and some observers seem disposed to lay upon them the whole blame for the propagation and spread of plague, which is held to be essentially a rat-borne disease. The susceptibility of rats has been noted from remote times and in many countries, particularly in China, but it has never attracted so much attention during the recent plague, and the results of plague investigations among rats in the London plague of 1891 showed that the mortality among rats was reported, and the broad fact that they do die of plague is incontestable. It is therefore easily intelligible that they may play an important part in multiplying and fixing the poison on a locality. As to how they convey it from man to man the greatest probability is in favour of the flea as an intermediary. Mortality among rats is said to precede the appearance of human plague, but the evidence of this is always retrospective and of a very loose character. At Sydney a careful investigation was made; and the conclusion reached by Dr Tilswell was that "there was no ground for even a suspicion that our epidemic was being maintained by any process of direct contagion between man and man," but that rats were the carriers. In Glasgow the experience was just the contrary. Personal connexion was traced in every case, and rats excluded; there was no mortality among them, and of 300 caught and examined none had plague (Chalmers). Similarly, at Oporto, personal connexion was traced in all the earlier cases; there was no mortality among rats, and no evidence to connect them with the outbreak (Jurge). Again, a comparison between rat-infected and rat-free districts in Bombay showed a much higher incidence of plague in the latter. A case against rats in Bombay, it is said, in which 50,000 or 60,000 were killed in a short time had no effect in checking the disease. Plague-rats have rarely been found in ships sailing from infected ports; and though millions of these animals must have been carried backwards and forwards from quay to quay between Hong-Kong, Bombay and the great European ports, they have not brought the disease ashore.

By far the most important communication on the rôle of rats in the spread of plague is formed by the "Report on the Plague Investigations in India" (Journal of Hygiene, vol. vi. No. 4; vol. vii. No. 3, 1907). The chief conclusions arrived at in the report as the result of experiments are the following:—

1. Healthy rats caught plague from infected rats when the only apparent means of communication between the two was the rat flea (Bdelecheops).
2. In 21 experiments out of 38, 55% of healthy rats living in flea-proof cages have contracted plague after receiving fleas collected from plague-rats or other diseased plague animals. It is evident that it is proved the rat flea can transmit plague from rat to rat.
3. Close and continuous contact of plague-infected animals with healthy ones does not infect the latter if fleas are excluded.
4. Should fleas be excluded at one time and starts and spreads in proportion to the number of fleas present.
5. Guinea-pigs set free in plague-infected houses become infected with the rat flea and develop plague in a certain percentage.
6. Fleas caught on plague-infected rats are able to infect rats placed in flea-proof cages.
7. Guinea-pigs placed in plague-infected houses do not contract plague if they are protected from fleas; those placed in cages protected by a border of sticky paper at least six inches in radius, which the fleas cannot jump over, do not contract plague; the others not similarly protected, do.
8. Chronic plague may prevail in rats.

On this report it may, therefore, be taken that aerial infection, except, perhaps, in pneumonic cases, may be excluded, and that the chief source of infection is the flea. It was also shown that animals may become infected through the faces of a flea which has fed on plague-infected rats. This may serve to explain the manner in which plague-infected linen and clothing may convey the disease. The report also considers it proved that the bacillus pestis multiplies in the stomach of a flea and may remain a considerable time within its host.

Browning Smith says the following facts are admitted as known. (1) Plague can be carried by fleas from an unhealthy rat. (2) A flea can retain the plague bacillus alive for seven or eight days. (3) Man is, in the majority of cases, not infected through the skin, though the puncture may not be seen. (4) The rat flea, when finding no rats, will attack man and it will also attack other animals.
Very little light has been thrown on the conditions which favour the prevalence of plague. We do not know why it has developed a diffusive activity of late years, nor why it has attacked some places and consistently passed by others, such as Singapore. The words "dirty" and "insanitary conditions" are much used, but such general terms explain nothing. Slingo, however, has several times been infected, but never taken hold, is probably quite so dirty and insanitary as Hong-Kong, and it is pertinently remarked by the Bombay Research Committee that filth per se has but little influence, inasmuch as "there occurred in the House of Correction at Byculla, where cleanliness is brought as near to perfection as is attainable, an outbreak which exceeded in severity that in any of the filthy chawls and tenements around." Again, in Oporto there is an area which combines every possible sanitary defect—dense overcrowding, great poverty, no light, no air, no drainage, no scavenging, water brought in buckets. Plague got into this quarter, but did not spread there; on the other hand, it appeared in other and vastly superior parts of the town. Yet in at least one case neither the patient nor the "contacts" were removed, but were all shut up in one room with a sentry at the door and another in the street. The seasonal variations have been well marked and extremely regular in Bombay. The disease begins to be active in late autumn or the beginning of winter, and reaches its height in February or March, dying down in the summer. Baldwin Latham made an elaborate examination of the meteorological conditions, and more particularly of the vapour tension, from which he draws the conclusion that the seasonal variations are due to exhalation from the ground. His observations are original and worth attention. A simpler explanation is that the people live more indoors, and are so more exposed to infection during the plague season. The curve shows two rises, one at the beginning of winter, and the other at the commencement of the monsoon, and at both these times the people are driven indoors. A broad survey of the epidemiological facts suggests some general conclusions. The outbreaks fall into two well-defined groups: (1) those in which the disease is destructive and persistent, (2) those in which its effects are slight and transient. In the former the poison clearly fastens on the locality, and gradually increases its hold. The place is infected, not merely the people in it; for if they evacuate it, the disease soon ceases among them, and if they return in a short time, they are again attacked. Now the poison is contained, as we have already seen, in the discharges from patients, and in such infected localities the standing conditions and the habits of the people combine to retain the discharges on the premises. The floors, mostly of mud covered with dung, are fouled with spittle, vomit, and urine, and, being seldom or never cleaned out, foster a gradual accumulation of poison, to which infected rats and the concealment of illness contribute. These are just the conditions which prevailed in Europe in the old plague days. They do not prevail now in those "white countries" which have been invaded but have repelled the attack with comparative ease and little loss. It may be concluded, with some confidence, from experience and theory alike, that localities where they do not prevail may fail to keep plague out, but have very little to fear from it, except the disturbance of trade caused by the traditional terrors that still cling to the name.

Prevention.—The principles are the same as those which govern the prevention of other infectious diseases. "Sanitary cords" and the like are obsolete. International procedure is supposed to be regulated by the Venice convention of 1897 (see QUARANTINE), but that instrument contains an optional clause allowing countries to do as they please with their own frontiers. Except Great Britain and France, all allowed quarantine in a more or less stringent form at seaports. It is generally used as a system of local extortion imposed upon travellers and shipping. According to the Venice convention, ships are divided into (1) healthy, (2) suspected, (3) infected. (1) Healthy are those free from plague throughout the voyage; (2) suspected, those in which plague has occurred, but no fresh case within twelve days; (3) infected, those in which plague has occurred within twelve days. Great Britain relies on medical inspection, removal of sick or suspected cases, and supervision of the healthy arriving on an infected ship; infected clothing is burnt and infected ships are disinfected. The procedure is the same for cholera, but it is directed by the director of the Plague. Ships passing through the Suez Canal are subject to similar inspection; sick persons are landed at Moses Wells, and suspected ones detained. The risk of importing plague from India has been materially lessened by medical inspection of outward-bound ships at the principal ports. This has been very thoroughly carried out at Bombay with good results. In 1897 pilgrimages from India to the Hedjaz were prohibited. By the Venice convention a number of articles of merchandise are classed as susceptible and liable to be refused admission, but the only ones which there is any reason to consider dangerous are used clothing and rags. A patch should be kept on rats at ports of arrival and on board ships from infected countries.

When plague is present in a place, the measures to be taken are the usual ones for dealing with infectious disease, with some additions. The sick and suspected should be removed in special ambulances to an isolation hospital, their soiled linen, &c., should be burnt, and the premises disinfected. Corrosive sublimate in an acid solution is the best disinfectant, but sulphuric acid, in 1:250, is efficient and cheaper. Suspected cases should be bestowed in a special isolated building until the diagnosis is fully determined. "Contacts" should be kept under observation. Rats should be exterminated as far as possible, especially by means of the Danysz virus, which spreads slowly through the community, even when the disease has been removed. The greatest care should be taken in dealing with the hospital linen and discharges from patients. Hospital staffs should be kept apart. Inoculation with Hoffkine's prophylactic fluid should be offered to all persons willing to avail themselves of it. It is especially desirable for hospital and ambulance staffs to be inoculated with a vaccine prepared from sterilized cultures of plague bacillus. Inoculation is harmless, and the results obtained in India justify a favourable opinion of its protective efficacy. At Hubli, where nearly the whole population was inoculated between the 11th of May and the 27th of September

The system of inoculation against plague with a fluid prepared from sterilized virus of the disease was introduced in India by Professor Hoffkine early in 1897. The composition of this fluid was determined by a search for a safer and cheaper method of preparing it than that produced by the French, who announced its employment to be free from danger, and it was used on a large scale in various parts of India without producing injurious effects. In September 1902 the standard method of making the Indian fluid was patented by the Indian government and the Indian Medical Research Institute on its own authority, with the object of expediting the process, and thus meeting the heavy demand then being made. This led to the establishment of a laboratory organization with a large scheme of inoculation. The change involved the omission of a proportion of carbolic acid which had up till then been added to the original fluid as a further precaution against contamination. The new fluid, for water agar process, contained no carbolic acid, other methods being relied upon to ensure its purity. On the 6th of November 1902, nineteen persons who had been inoculated on the 9th of October in the village of Mallkowal from a single bottle (5 ml.) of the Indian fluid containing only 0.5 mg. of the germ of tetanus, and all of them subsequently died. A commission, consisting of Sir Lawrence Jenkins, Lieut.-Colonel Bomford, M.D., principal of the Medical College, Calcutta, and Major Semple, Secretary of the Indian Medical Research Institute of the United Provinces, was appointed by the government of India to inquire into the disaster. They found that the germ of tetanus had been introduced into the fluid before the bottle was opened at Mallkowal, and they thought it probable that this might have occurred owing either to insufficient sterilization or to the process of filling the bottle from a larger flask having been performed with defective precautions. They examined the cases and declared the opinion that carbolic acid was a valuable agent in restraining tetanus, but that on account of its irritant action, and that, therefore, thought that its omission was a grave mistake. Experiments undertaken in India by two independent inquiries appeared to confirm the view, and their conclusions, together with the data on which they were based, were submitted with the report of the commission for examination and further experiment to the Lister Institute in London. With reference to the findings of the Mallkowal commission the Institute were asked to report (1) on the comparative efficacy of the standard and new fluids as a
1808, the mean mortality among the inoculated was 1·3%; among the uninoculated 13·2%. At Daman the mortality was—
inoculated 1·6%, uninoculated 24·6%; at Dharwar, inoculated 1·2%, uninoculated 5·2%. In all these cases the numbers dealt with were large and the test fair.

Simpson, in *The Practitioner* (Dec. 1906), gives an analysis of the results of Haffkine's serum inoculations as follows:

In Poona, out of 5953 uninoculated cases the incidence was 6·8%, while in 1300 inoculated cases it was only 0·33%. Klein also prepares a new prophylactic from the dried organs of a guinea-pig, and one of the most interesting experiments is that of Strong (*Archiv für Schiffs- und tropische Hygiene*, April, 1906), who uses for producing immunity in man a living virulent culture of the bacillus. For the control of smallpox he finds out the mishap and with no more unpleasant results than those occurring after vaccination. Inoculation protects against attack, and greatly modifies the illness when it fails to protect. How long the protection lasts has not been determined, but it appears to be several months at least.

The main authorities for the researches into plague are in the official reports of recent years from India and elsewhere. See generally W. J. Simpson, *A Treatise on Plague* (1906).

**PLAICE**—**PLAIN SONG**

**PLAICE** (*Pleuronectes platessa*), a species of flat-fish, common on the coasts of northern Europe from Iceland to the Bay of Biscay. It is readily recognized by the yellow or orange-coloured spots which are placed in a row along the dorsal and anal fins, and scattered over the body. The eyes are on the right side, and the teeth in the jaws compressed and truncate. The scales are minute and smooth. Plaice, like other flat-fishes, prefer a sandy flat bottom to a rocky ground, and occur in suitable localities in great abundance; they spawn early in spring, and are in finest condition in the month of May. Individuals of seven or eight pounds weight are considered fish of large size, but specimens of double that weight have been caught.

See the monograph by F. J. Cole and J. Johnstone (Liverpool, 1901); and W. Garstang's "Reports on the Natural History of the Plaice" (*Revue et procès-verbaux du conseil international pour l'exploration de la mer, 1905 seq.*).

**PLAID** (*Gael. plaide*, Ir. *ploid*, usually taken to be derived from Gael. *peall*, sheepskin, Lat. *pelts*, skin), an outer garment, consisting of an oblong piece of woolen cloth, which has formed the principal outer part of the costume of the Highlanders of Scotland. The wearer wrapped himself in the plaid, the lower portion, reaching to the knees and bolted, forming the kilt. Later the lower portion was separated, being called the *phiti-bog*, the plaid being used as a covering for the shoulders and upper part of the body. The plaids were usually of a checked or tartan pattern. The word is thus used of any cloth made with such a pattern. "Shepherd's plaid" is a cloth with a chequer of black on a white ground.

**PLAIN** (O. Fr. *plain*, from Lat. *platum*), a level surface; hence in physical geography a tract of country generally quite flat or comparatively so (see GEOGRAPHY). The adjective "plain" signifies "level," and thence smooth, clear, simple, ordinary, &c.

**PLAINFIELD**, a city of Union county, New Jersey, U.S.A., 24 m. W. by S. of New York City. Pop. (1910 U.S. census) 20,550. It is served by the Central Railroad of New Jersey and by electric lines connecting with neighbouring towns. It is situated for the most part on a plain; north-east are heights occupied by the suburb of Netherwood, and north in Somerset county, on the slope of the first Watchung Mountain, is the borough of North Plainfield (pop. 1910 U.S. census 6117), which forms with Plainfield virtually a single residential and business community. Plainfield is one of the most attractive residential suburbs of New York. The city has an excellent public school system, a good public library, with an art gallery. The Longwood driving course and the driving track are features of the city. The value of the factory products increased from $2,437,434 in 1900 to $3,572,134 in 1905, or 46·6%. Plainfield was settled in 1684, but it was not until 1735 that the first frame house was erected. In 1760 a grist mill was erected, and for several years the place was called Milltown. The township of Plainfield was created out of Westfield township in 1847, and in 1867 Plainfield was chartered as a city.

**PLAIN SONG, or Plain Chant** (*Gregorian Music*; Lat. *cantus planus*; Ital. *canto gregoriano*; Fr. *plaine chant*), a style of unisonous music, easily recognizable by certain strongly marked characteristics, sometimes ancient fragments of which are believed to have been in use under the Jewish dispensation from a remote period, and to have been thence transferred to the ritual of the Christian Church.

The theories advanced as to the origin of this solemn form of ecclesiastical music are innumerable. The most widely spread opinion is that the older portion of it originated with the Psalms themselves, or at least sprung from the later synagogue music. Another theory traces the origin of plain song to the early Greeks; and the supporters of this view lay much stress on the fact that the scales in which its melodies are composed are named after the old Greek "modes." But, beyond the name, no connexion whatever exists between the two tonalities. Older hypotheses attribute the origin of the plain song to the Phoenicians, to the Egyptians, to the early Christian converts, and to the musicians of the middle ages.
Towards the close of the 4th century Ambrose of Milan, fearing the loss or corruption of the venerable melodies which had been preserved by means of oral tradition only, endeavoured to write down their primitive purity, and to teach the clergy to sing them with greater precision. A still more extensive work of the same nature was undertaken, two centuries later, by Pope Gregory the Great. And thus arose two schools of ecclesiastical music, still known as the "Ambrosian" and the "Gregorian chant"—the first of which is practised only in the diocese of Milan, while the latter is universally accepted as the authorized "Roman use." In order to explain the essential differences between these two schools, we must describe in detail some of the peculiar characteristics of plain song.

The melodies which form the répertoire of plain chant are not written in modern major and minor scales, but in certain tonalities bearing names analogous to those of the early Greek "modes," though constructed on very different principles. Of these "modes," fourteen exist in theory, though twelve only are in practical use. The intervals of each "mode" are derived from a fundamental sound, called its "final." The compass of each mode comprises eight sounds—that of the first, third, fifth, seventh, ninth, eleventh and thirteenth "modes" extending to the octave above its "final," and that of the second, fourth, sixth, eighth, tenth, twelfth and fourteenth extending from the fourth note below the final to the fifth note above it. Consequently, eight of the tonalities, called the "authentic modes," occupy the lowest place in each system of sounds, and those of the second series, called the "plagal modes," the middle place—the same "final" being common to one "authentic" and one "plagal mode." The following table exhibits the entire system, expressed in the alphabetical notation peculiar to modern English music—the "final" being indicated in each case by an asterisk, and the position of the semitones, from which each mode derives its distinctive character, by brackets.

Nos. 11 and 12 in this series are rejected, for technical reasons into which we have not space to enter; they are practically useless.

Of these modes Ambrose used four only—the first four "authentic modes," now numbered 1, 3, 5 and 7. Gregory acknowledged, and is said by some historians of credit to have invented, the first four "plagal modes"—Nos. 2, 4, 6 and 8. The use of the remaining "modes," except perhaps the ninth, was not formally authorized until the reign of Charlemagne, who published an official decision upon the subject. In one or other of the twelve "modes" recognized by this decision every plain-chant melody is composed. The number of such melodies preserved to us, the genuineness of which is undoubted, is very large; and the collection is divided into several distinct classes, the most important of which are the melodies proper to the Psalm-Tones and Antiphons; the Ordinarium Missae, the Introits, Graduals and Offertoria; the Prefationes, Versiculi and Responsoria; the Hymns and Sequences; and the Lamentations, Exsultet and other music used in Holy Week.

Of these classes the most interesting by far is that which includes the psalm-tones, or psalm-tunes, called by modern English historians the "Gregorian tones." The oldest of these are tones 1, 3, 5, 7, and 9. The remaining tones 2, 4, 6 and 8 is less firmly established, though there is no doubt that Gregory the Great sanctioned their use on strong traditional evidence. In addition to these, a peculiarly beautiful melody in mode 9, known as the Tonus peregrinus, has been sung from time immemorial only to the psalm In exitu Israel.

The oldest version of this melody now extant is undoubtedly to a certain extent impure; but tradition imparts to it a very high antiquity, and even our doubts as to the precise form of the now generally accepted reading extend only to one single note. A widely accepted tradition points out this melody as the tune sung to In exitu Israel, as part of the Great Hallel (see PSALMS), which is generally (but hardly rightly) identified with the hymn sung by Christ and His apostles immediately after the Last Supper.

One very powerful argument in favour of the Jewish origin of the psalm-tones lies in the peculiarity of their construction. It is impossible to ignore the perfect adaptation of these venerable melodies to the laws of Hebrew poetry, as opposed to those which are modern. The division of the tune into two distinct strains, exactly balancing each other, points assuredly to the intention of singing it to the two contrasted phrases which, inseparable from the constitution of a Hebrew verse, find no place in any later form of poetry. And it is very remarkable that this constructional peculiarity was never imitated, either in the earliest hymns or antiphons we possess or in those of the middle ages—evidently because it was found impossible to adapt it to any medieval form of verse—even to the Te Deum, which, though a manifest reproduction of the Hebrew psalm, was adapted by Ambrose to a melody of very different formation, and naturally so since so many of its phrases consist of a single clause only, which, when sung, divides into the following verses:

This peculiarity now passes for the most part unnoticed; and the Te Deum is constantly sung to a psalm-tone, very much to the detriment of both. But in the middle ages this abuse was unknown; and so it came to pass that, until the "School of the Restoration" gave birth, in England, to the single chant, avowedly built upon the lines of its Gregorian predecessor, and a somewhat later period to the double one, so constructed as to weld two verses of the psalm into one, often with utter disregard to the sense of the words, the venerable psalm-tones stood quite alone—the only melodies in existence to which the psalms could be chanted. And so intimate is the adaptation of these plain-chant melodies to the rhythm as well as to the sense of the sacred text, even after its translation into more modern languages, so strongly do they swing with the one and emphasize the other, that it is difficult to believe that the composition of the music was not coeval with that of the poetry.

Next in antiquity to the psalm-tones are the melodies adapted to the antiphons, the offertoria, the graduals and the introits, sung at High Mass. Those proper to the Ordinarium missae are probably of later date. Those belonging to hymns and sequences are of all ages. Among the latest we possess—perhaps the very latest of any great importance—is that of Laudas Sion, a very fine chanted melody in modes 7, 8 and 9, and the celebrated sequence written by Thomas Aquinas about 1267.

To the melodies adapted to the Lamentations and the Exsultet, as sung in the Church of Rome during Holy Week, it is absolutely impossible to assign any date at all. We all know that they are of extreme antiquity, and beautiful beyond all description. The melody of Exsultet is, indeed, very frequently cited as the finest example of plain song in existence.

To assert that melodies so old as these have been handed down to us in their original purity would be absurd. But the presence of corruption rarely passes undetected by the initiated; and vigorous efforts have been made from time to time to purify the received text by reference to the oldest and most trustworthy MSS. attainable. Such an effort was begun on a very extensive scale by the "Congregation of Rites," at the instigation of Pope Pius IX., in the year 1868; and the labours of that learned body, together with those of the monks of Solesmes and elsewhere, have done much towards the restoration of plain chant to the highest state of purity possible. In England the Plain-Song and Medieval Music Society, founded in 1888, has also done valuable work by its publications. (W. S. R.)

**PLAINTIFF.** One who brings a "plaint" (Low Lat. planta flangere, beat the breast, lament), the name, in law, of the party who brings an action against another, who is called the
PLAIT—PLANARIANS

"defendant." In suits for divorce the party bringing the suit is styled the "petitioner," the party against whom it is brought the "respondent."

PLAIT (through O. Fr. plait, from Lat. plicatum, folded, plaited, or to fold), properly a fold, especially a fold of cloth, now usually in the collateral form "pleat." It is not principally applied to entwined strands of ribbon, hair, straw or fibre.

PLAN (from Lat. planus, flat), a diagram on a flat surface; hence by analogy any deliberate scheme or design. In architecture, a "plan" is a horizontal geometrical section of the walls of a building, or indications, on a horizontal plane, of the relative positions of the walls and partitions, with the various openings, such as windows and doors, recesses and projections, chimneys and chimney-breasts, columns, pilasters, &c. This term is sometimes incorrectly used in the sense of design (q.v.).

PLANARIANS, a well-defined group of animals, characterized externally by their ovoid or vermiform shape, their gliding movements and their soft, unsegmented, ciliated bodies: internally by that combination of low somatic type of structure and complex gonial organization which is characteristic of the Platyelmnia (q.v.). Their low type of bodily structure may be exemplified by the fact that the mouth is the only means of ingress to and egress from the blind alimentary sac, and that no vascular system is differentiated. Most Planarians are aquatic and the cilia that cover the body produce by their beating a stirring of the water. Hence the class is generally known by the name Turbellaria.

Planarians form one of the basal groups of the animal kingdom.

They are the simplest of multicellular creeping things. In them the gliding movement has become habitual. The lowest Planarians are still largely free-swimming animalcules and we can trace within the limits of the group the development of the creeping habit and the consequences that flow from it. It has led to the differentiation of anterior and posterior extremities; to the formation of bilateral symmetry; and to the development of a mucilage protecting the body against friction. It entails the concentration of the scattered nervous system on the ventral surface and at the anterior end, and it has induced the segregation of the diffused sense-organs in the head. The Planarians occupy a position midway between the simple planula larva of Coelenterates and the segmented Annelids. They have probably sprung from an early Cœlomate stock, or represent an independent class descended from a two-layered parentage distinct from that of the Coelenterates; a view which is adopted in the present article.

Occurrence.—Most Turbellaria are aquatic. They abound on the seashore and in fresh water, amongst weeds or under cover of stones, shells and sand. Few of them are pelagic or deep-water forms, and only some half-dozen Planarians are known to be parasitic. A large number of land Planarians are known, chiefly from tropical and southern temperate countries.

The majority of marine Planarians are nocturnal or cryptozoic, hiding away during the period of low tide to avoid desiccation of their soft silky bodies and coming out at night or during high tide to feed. They are mostly carnivorous, and their movements are correlated largely with the nature of their food. The smaller, more active species occur in companies amongst the finer sea-weeds over which they creep or swim in pursuit of their food. The larger marine species occur singly or in pairs on Ascidians, Nullipores or Polyzoa, from whence as the tide rises they issue to feed. By the time the next low tide exposes them, these Planarians have so completely digested their meal that we know very little of its nature. The common fresh-water Planarians form either little companies of a dozen or more, usually of a single species, huddled together under a stone or in some cranny (see under "planula"), or societies of several species that inhabit Spiatum and other fresh-water vegetation. This fresh-water planarian fauna is of two kinds, the fauna of permanent and that of temporary sheets of water and both show a certain adaptation to their environment. The latter, being subject to greater extremes of temperature than the lacustrine Planarians, produce

1 These references are to the literature at the end of this article.

thick-shelled eggs only. The development of these eggs is rapid in warm water, slow in cold; so that a pool after a few days of early spring sunshine is soon populated and provision is made for the continuance of the race should a cold snap follow. The lacustrine Planarians exhibit a different form of adaptation. The eggs laid by many of these animals are either thin-shelled and rapidly hatched or thick-shelled and slowly hatched. The lake-water, however, is, in spring, even after sunshine, of a much lower temperature than that of pool-water, but the masses of Spiatum and other weeds that border lakes and marshes are often warmer than the open water and may be as much as 15° or 15° C. higher in temperature. Here the Planarians assemble to benefit by the warmth, and under such favourable conditions lay thin-shelled eggs which rapidly develop; whilst in colder surroundings or at the onset of winter thick-shelled resting eggs are laid. In this manner we can understand the abundance of Planarian life in cold meres and transitory pools in Great Britain, Scandinavia, Finland, Denmark and North America.

In contrast to the general habit among Turbellaria of haunthing dim or dark places, the station chosen by a few species is exposed and strongly illuminated. The marine Convoluta and Polychaerus and the fresh-water Vortex viridis may be taken as examples. Convoluta paradors occurs among brown weeds which receive much light during neap tides and strong direct sun or light every fortnight. Polychaerus creeps about the New England shore without resorting habitually to cover, and is also strongly insulated. Vortex resembles the green Hydra of our ponds in choosing the lightest side of its surroundings; and finally, Convoluta rosea frequents points the beach green in Brittany, part of Normandy and Natal. In every such case the Planarian is coloured brown or green by the presence of photosynthetically active cells and the singular heliotropic habit of these Turbellaria is associated with the illumination necessary for the activity of their coloured cells.

Only one branch of the Planarians has become terrestrial, but this has spread over almost all the whole globe. One species (Rhynchodemus terestris, fig. 1, e) is fairly common in Great Britain under stones, logs and occasionally on fungi, but the Holarctic countries (North America, Europe and North Africa, North Asia) are extremely poor in terrestrial species. In countries lying in the centre and in the south of the great continents and in the south temperate continental islands and archipelagoes these land Planarians become more abundant and varied; and being frequently transported with earth or plants they are often found in hothouses and botanical gardens far from their native country. Their distribution offers some points of special interest showing a close relationship between the South American fauna and that of Australia and New Zealand: between the land Planarians of Madagascar, of Ceylon and of Indo-Malaya: and a marked contrast between Japan and the rest of the Palæarctic region (see Von Graff [1], 1899).

External Characters.—Planarians range from the minute forms no larger than Infusoria to ovate, marine species, 6 in. in diameter and to ribbon-like land forms 8 in. in length. The majority are small, somewhat cylindrical organisms with a flat creeping surface. Others, comprising the common fresh-water and marine forms, are flattened and leaf-like, often provided with a pair of tentacles near the front end of the body, and in some cases the whole dorsal surface is beset with papillae. The land forms are elongate and smooth, and their anterior extremity is often modified into the arcuate shape of a cheese-cutter. Their movements are usually of a gliding character. The minuter forms perform short excursions into the water round their station, and in so doing recall Infusoria. The larger forms, in addition to gliding like pellicles, fold the expanded anterior part of their body into a couple of fans, with which they swim after the fashion of a skate. The folded margins of other forms clasp the weeds on which they live. Adhesion is effected by the mucous investment of the body and frequently by some specially developed local secretion of slime, or by a sucker. By these means, aided by their
algal-frequenting and cryptic habits, the Turbellaria, though soft-bodied, are able to withstand the violence of the waves.

The anterior end in all Turbellaria is the site of the chief sense-organs, and in some forms (Proboscidia) becomes transformed into an invaginable proboscis of highly tactile nature. Such forms lead naturally to the Nematina (p. 276).

Coloration.—The coloration of Planarians is of interest. The flattened marine forms are often brilliantly coloured on the dorsal surface, either uniformly or with some striking marginal band; or they may exhibit longitudinal bands of contrasting tints or a mottled appearance. The significance of these colours is not fully understood, but in some cases of sympathetic coloration the derivative function of the pigments is probably to aid cryptic resemblance. The terrestrial Planarians exhibit the most striking patterns in longitudinal striping and cross-bars which appear to have no relation to the environment of these essentially nocturnal animals. The fresh-water forms are colourless or dusky, often dark-brown, possibly in relation to the retention of heat; but in a number of both fresh-water and marine Planarians a green colour is present, constantly in some species, sporadically in others.

This green effect is due to the infection of the Planarian by a minute alga which multiplies in the tissues and may profoundly affect the habits and even the structure of its “host.” The planarian so affected acquires a heliotropic habit; it becomes gregarious and in extreme cases ceases to ingest solid food. In Convoluta roscoffensis the green cells have become indispensable. They function both as the nutritive and excretory organs of the Planarian, and the young animal cannot develop until it is infected and has acquired a supply of these green cells which become incorporated into its tissues (Gamble and Keeble [7]). Brown algal cells (Zooxanthellae) are known in other species of, Convoluta.

Food.—The food of Turbellarians consists, in the smaller species, of diatoms, unicellular algae, microscopic animals and other Turbellarians; in the larger ones, of worms, mollusca and insects. The fine feeders capture their food chiefly at night by gulping down the minute organisms that settle or swim in their neighbourhood. The coarse feeders enclose their prey with a coating of slime and then proceed either to engulf it in their expansible mouth or to perforate it by their trumpet-like pharynx. The mouth is remarkably variable in position (fig. 2). In many flattened Planarians it is placed centrally on the ventral surface somewhat as in a jelly-fish. In the majority it is nearer the anterior end, but in a few remarkably elongate forms it occupies a position near the hinder end of the animal. In the cylindrical forms (Rhabdocoels) a similar variability in the position of the mouth is met with.

Anatomy.—The structure of the Turbellaria though greatly varied in detail, conforms to a single type of somatic organization which is transitory in the higher invertebrates. The sexual organs, on the other hand, are founded on two or more types, and the astounding complications of these structures suggest that their evolution has been governed by quite other factors or combinations of factors than those that have guided the somatic evolution of the group.
respiratory organs are developed, probably in correlation with the absence of a blood-vascular system. On the other hand, the process of reproduction is elaborately organized. The Planarians are hermaphrodite and, as in so many other small animals, the body, after attaining maturity, becomes in many Planarians practically a genital sac and is soon exhausted by the repeated cells upon its reserves that are involved in the rapid production of eggs and spermatozoa. The intervals between successive clutches has been found in *Compsa rosea-sennis* to be a month, thus suggesting the influence of the lunar months upon reproduction.

**Integument.**—The epidermis is ciliated and highly glandular. It consists of a single layer of cubical or oblong cells with the structure seen in fig. 3. The glandular secretion takes various forms, such as mucinoid granular blocks, or fusiform refringent homogeneous rods. These rods or "rhaditides" are classification of the Planarian is based on them. Thus we have the Rhabdocoelida with straight gut and the Tricladida and the Polycedida with triple and multiple branches to the gut. The Rhabdocoelida are further divided into three groups: the Acoela

**Fig. 4.**—Portion of a transverse section of *Mesostoma ehrenbergii* (X800).

The epidermis (E) consists of cells divided into an outer and inner zone. The latter containing rhaditides (Rb); the cilia (C) are thickened about the middle of their length. Below the epidermis is the basement-membrane (BM), a layer of circular muscles (C) and of longitudinal ones (L). Below this again is the mesenchyma (M), made up of branched cells and dorsal-ventral muscle fibres (DM), the mesenchymatous glands (Rmc) are producing rhammites (Rm) which pass outwards.

![Image of transverse section of Mesostoma ehrenbergii](image)

**Fig. 6.**—Main trunks of the Excretory System of *Mesostoma ehrenbergii*. O. Sch., opening to the exterior through the mouth; ph, Pharynx.

with a simple syncytial gut not sharply separated from the surrounding mesenchyma; the Rhabdocoela, with a hollow gut and a peri-vascular schizocoelic space; and the Alloeocoela with a lobate gut and reduced schizocoel. The last group leads one naturally to the Tricladida; the Polycedida being an independent group.

The pharynx varies widely in structure. In the Acoela it is a mere thickening and pitting of the integument. In the Rhabdocoela a great number of elaborate modifications are found. These are based on the type of a buccal invagination, which forms the pharyngeal sheath, and from the bottom of this there springs a muscular outwards directed tube or fold. In the Alloeocoela and Tricladida the pharynx is an elongate protractible cylinder, and in the Polycedida it may be an immensely distensible frilled organ, the folds of which have independent movement, or an elongate tube. At the base of the pharynx lie the openings of salivary glands. In the Polycedida the section of the alimentary canal into which the pharynx opens is a median stomach from which the intestinal branches radiate. The stomach in few forms is provided with digestive glands. The branches possess an independent musculature and exhibit active peristalsis. The intestine of Planarians is not ciliated, and digestion appears to be largely intracellular and not caviatory.

**Mesenchyma.**—The mesenchyma (Bohmg.: parenchyma anelli) consists of a mass of branched vacuolated cells, imbedded in which lie gland-cells, pigment-cells and the excretory system. It envelops the genital organs, which though in the mesenchyma are not of it, and it forms an investment to the gut and to the space (schizocoel) which often occurs between the gut and the mass of the mesenchyma. The mesenchymatous gland-cells are of different kinds. (1) Single cells in which rods (rhammites) are developed (fig. 4, Rmc). Such cells in embryonic life give rise to a process which perforates the soft basement-membrane and penetrates between the epidermal cells. The process becomes hollow, and the rhammites pass outwards along it on to the surface of the animal, forming in many Turbellarians thickly set rows of rods on the head. (2) Similar cells contain nematocysts in a few Planarians (*Microstoma, Stenostoma, Anomyus virilis* and *Styroclena tarda*). Whether these...
nematocysts develop in the Turbellarian is doubtful, and it is not impossible that they are derived from the tissues of some coelenterate animals eaten by the Planarians, as has been shown to be the case in the nematocysts of Codium. (3) Cells producing aciculate spicules, sometimes associated with a spiral thread. These structures are often associated together in batteries, notably so in the remarkable genus Acoela.

Excretory System. —The excretory system consists of protonephridia, that is, of tubes opening to the exterior by one or more concretion lying in a fluid. From what is known of these organs in higher invertebrates we may infer that they serve to increase the perception of slow wave-movement and enhance the control of the muscular sense.

Eyes are generally present in Planarians. Two types are distinguishable—eyes with a cup-shaped retina facing outwards, and those with an inverted retina facing inwards. The former occur in Triclads and Polyclads around the margin of the body often a hundred or more may be present. The latter occur in all groups except the Acoela, but are limited to the neighbourhood of the brain or basis of the nuchal tentacles. Recent investigation has shown that the essential part of the eyes has in all cases a complicated structure and is not a mere epidermal cell-group enclosed by pigment and provided with an optic nerve. On the contrary (Hesse [10]), adequately known eyes are composed of rod-cells that contain each an axon filament or bundle of fibres (the termination of the nerve), and the distal end of the rod-cell is converted into a straitened usually broad border, where the action of light commences. A group of such specialized rod-cells is enclosed in a pigmented cup opening either outwards or inwards and pierced by an optic nerve.

Reproduction. —All Turbellaria are hermaphrodite, and reproduce sexually, but a few forms (Microstomidae and some Triclads)

**Fig. 10.** Microstoma lineare, Oe. undergoing division. There are 16 individuals, 8 with mouth apertures, showing the buds of the first (m), second (m'), third (m*), and fourth (m**) generation. The fifth generation has not yet acquired a mouth aperture. c, ciliated grooves; e, eye spots; t, intestine.

The oocyst occurs constantly in every other division of the group. It is with one exception a single median organ placed over the brain, and consists of a uni- or bi-cellular sac containing a calcareous concretion lying in a fluid. From what is known of these organs in higher invertebrates we may infer that they serve to increase the perception of slow wave-movement and enhance the control of the muscular sense.

**Fig. 11.** Plan of an Acoela Turbellarian.

- c, Eye.
- m, Mucous gland, formerly mistaken for the mouth, which lies in the centre of the body.
- ol, Otolith.
- o, Ovary.
- p, Digesting parenchyma.
- l, Testicular follicles.
- vs, Vesicula seminalis.
- d, Male-organ of copulation.
- e, Female-organ of copulation.
- f, Common sexual aperture.
- fc, Bursa copulatrix.
- cn, Brain.
- e, Eye.
- g, Germanium.
- i, Intestine.
- ln, Longitudinal nerve trunk.
- m, Mouth.
- ph, Pharynx.
- rs, Receptaculum seminis.
- s, Salivary gland.
- t, Testis.
- u, Uterus (containing an egg).
- v, Yolk gland.
- vs, Vesicula seminalis.
- o, Common copulatory organ.
- y, Common sexual aperture.
- bc, Bursa copulatrix.

increase during the summer by fission and during the winter by eggs. The body of the Microstomidae becomes constricted and partially subdivided into two, the posterior half regenerating a brain and pharynx. Subsequently each becomes again converted into two zooids, and the process is repeated until a chain is formed as in fig. 10. This breaks up into its constituent members, each of which repeats the process until the onset of reproduction. The
Triclads, on the other hand, fragment, without undergoing preparatory changes.

The male and female genital ducts (gono-ducts) open to the exterior, either through a common chamber on the ventral surface (most Rhabdocoelida and all Tricladiida, figs. 12, 14) or by separate apertures that are also usually ventral. In the latter case, the male gonopore is usually in front of the female one (all Polycladida and some Rhabdocoelida). A separate opening is sometimes acquired by one or other of the accessory reproductive organs (as by the spermotheca in some Rhabdocoelida in which it is dorsal).

The generative organs of the Planarians are complex. Male and female germ-cells develop in one and the same individual and reach the exterior by independent ducts. These ducts are provided with accessory glands along their course and terminate in penial or vaginal structures, often of great complexity, which are surrounded by an "atrium" or invagination of the ventral body-wall. From this invagination a special vesicle "uterus" is often developed for the reception of the fertilized egg previous to oviposition.

The Acoela present the simplest arrangement. In this group (fig. 11) the male germ-cells arise in follicles each of which is the product of a single sperm-mother-cell. From these follicles, the motile spermatozoa enter the paired sperm-duct, which opens by a single aperture near the hinder end of the animal, and is provided with a simple unarmed glandular penis. The female germ-cells or ova arise from a paired ovary, some of the cells of which appear to act as nurse-cells, supplying the young eggs with nourishment. When mature the eggs are transferred to the oviduct. At the point where the two oviducts join in order to open to the exterior they receive a conical sac (spermotheca) which contains spermatozoa. At this point the eggs are fertilized, and deposited in a mucilaginous mass which is attached to algae or buried in the sand. It is characteristic of the Acoela that the testes and ovaries should not be continuous with either the sperm-duct or the oviduct respectively.

In one genus of the Acoelous Turbellaria—Polyceraurus—this primitive arrangement undergoes a development which foreshadows the complicated ovaria and vitellaria of higher forms. In Polyceraurus the eggs mature in a special roomy chamber and are here provided with yolk which is elaborated by a sterile part of the ovary. Thus we have a differentiation of germ-cells into two portions allocated to two chambers: fertile ova which open eventu-

ally into the oviduct, and sterile ova that become yolk-cells and open into the brood-pouch.

The remaining Rhabdocoelida possess separate ovaries and yolk-glands. The union between the two sets of ducts takes place in the genital atrium which is provided with a spermotheca for the fertilization of the ova, but in at least one sub-family (Cylindrostominae) the spermotheca opens by a special dorsal pore. These ova, together with the yolk and spermatozoa, are then transferred to another atrial dcvorculum—the uterus, in which a shell is formed and from which they are deposited in the form of a cocoon. In addition, a muscular sack, the so-called "bursa copulatrix," is usually present. The male organs of Rhabdocoelida are no less complex. The testes are either follicular (Allocoela) or compact.
the uterus—which may either be a dilatation of the common oviduct (vagina) or of the atrium, and may open to the exterior independently (single in *Umbilicostomum*). In *Byellocura* the uterus is said to act as a spermotheca. In addition to these structures, accessory muscular organs are found in *Dendrocoelum* and developed to a high degree in Planarians, which possess the so-called adnecohoi and adnecodonty (see von Graff, 1898).

Lastly, the Planarians offer certain distinctive sexual characters. The ovaries are follicular, very rare is the ovary differentiated into a single ovary of their own yolk (fig. 15). The oviducts open into a chamber which, after receiving a voluminous shell-gland, opens by a muscular bursa to the exterior. No special uterus is developed, but from the point of union of the two a two-lobed and often annular organ, which may open separately to the exterior (Trigonoporus). The segments are equally disposed and the seminal vesicles usually form a median muscular eversible sac which opens in front of the female genital pore. In *Strobilonomoea* the female pore, the oviducts and the seminal vesicles opens through the mouth, as in certain Rhabdocoela. Moreover, it may be paired (Thysanozoon) or multiple. Thus in *Anynemus* twelve or more pairs occur. In *Cryptocotyle* the female organs are two, four or six may be present, but in this genus they all lie in a common sac. In *Polyostya* twenty pores occur rather about the female pore, but the most posteriorly placed of these structures are devoid of a seminal duct. This condition supports the view that in *Byellocura* the penis was at first a glandular organ probably used for attacking prey and that it has become secondarily connected with reproduction. In confirmation of this conclusion we have the observations of Lang (5) that *Yugia* strigilis lays a sac of spermatozoa with its penis when brought into contact with them. (See Whitman [9]). The genus *Laiailia* differs from all other Planocelis in possessing a genital opening.

The development of the Planarians is fairly well known. Except for one or two species of Planarians, development is direct and without metamorphosis. In *Typhloplanus* and *Funga* the embryo develops eight strongly ciliated lobes which form a circunferal band of larval processes. These have been compared with the girdle of Trochosphere larvae and also with the eight rows of swimming plates in Ctenophores. From the name of the individual the larvae are called Müller's larvae (fig. 16).

In the Rhabdocoela the eggs are usually laid in a shell which has characteristic shapes. Each capsule contains a single ovum and several yolk-cells. Segmentation, the formation of the disorganized megayocytes and microocytes. The latter give rise to the epidermis which is laid down in the blastula stage. The blastomere of various internal organs. There is no distinction of germ-layers, and the gut is gradually differentiated from the mesoderm, the formation of various internal organs. The development of the Planocelis larva has been described by Uijian as belonging to the Acoela.

The development of the Tricladida offers other peculiarities. Frequent cases of development occur by several amoeboid yolk-cells in each cocoon. Each egg-cell divides; but, as happens in the capsule ova of certain Mollusca and Oligochaeta, they do not all survive, some being used up as food by the remainder. The blastomeres of these develop into germ-layers, the blastomeres moving apart from one another. The details of organ-formation are still imperfectly understood.

The eggs of the Polycelis are laid somewhat like those of the Acoela. In the higher Planocelis, each cocoon yolk and an egg-shell which may be operculate. The majority of species go through a direct development. The segmentation of the egg in *Discocelis* and *Leptocelis* has been worked out by Lang and his results re-interpreted by Wilson and others (Hubrecht [12]). In Polycelis a distinction of germ-layers similar to that existing in the development of the Tricladida and certain other Invertebrates, is early apparent. The ovum by unequal segmentation gives rise to megameres and microthers, and between the two, intermediate cells form one origin for the digestive tube of the adult Planocelis. Two lateral placoid macromeres. The latter undergo division into hypoblast cells and yolk-masses. The similarity of cell-lineage in Polycelis and Coelomate Invertebrates, together with the tropocelis larval form (Müller's larval form), have been the two chief arguments in support of the view that this group is a link between the Planocelis and Coelomata. It is at present, however, doubtful whether such highly organized intercalary organs as the testes, are also present in certain Polycelis. Their relations to other turbellaria are quite uncertain, and on present evidence it seems legitimate to hold that they are the most highly differentiated division both in embryonic and adult structure.

**Systematic Arrangement.**

Order Turbellariia.—Free-living Platyhelminthes with a ciliated epidermis. Most of the larvae are designed to a two-layered Gut

**Sub-order A. Rhabdocoela.**—Gut syncytial or tubular. Female gonads always compact.

**Sub-order B. Dendrocoelu.**—Large forms with flattened body, branched intestine, follicular testes and follicular ovaries or compact ovary. One order except Platyhelminthes. The eggs of some species. Moreover, all marine except Platyhelminthes. Gastropods and Holothurians.

**Sub-order C. Allocoelu.**—Gut and parenchyma distinct. Intestine straight or lobate. Testes follicular. Penis and pharynx pharynx elongate, occasionally protruded through a common opening. Marine and fresh-water. Many fresh-water forms infected by all marine except Platyhelminthes. Phyllostomida, Gymnophoria.

**Sub-order D. Polycelis.**—Body leaf-like. Intestine composed of a median stomach with many branched or reticulate coeles; testes and ovaries follicular; genital openings usually separate, the male with one pair of gonopores, the female with two. All marine and widely distributed; some genera cosmopolitan.

**Sub-order E. Polycelis.**—Body leaf-like. Intestine composed of a median stomach with many branched or reticulate coeles; testes and ovaries follicular; genital openings usually separate, the male with one pair of gonopores, the female with two. All marine and widely distributed; some genera cosmopolitan.

**Appendix to the Turbellaria.**

Class Trematocoela.—This small class of Platyhelminthes possesses a strong resemblance to the Turbellaria (and in particular the Vorticellid rhabdocoelae) with the Trematoda. At the same time the Trematocoelidea present certain peculiar structural features which entitle the class to an independent position. The body is divided into the digitate tentacles which occur on the anterior or lateral margins of the body. The body measures about 5 mm. in length, and the flattened ventral surface is armed with a sucker. It presents the structure of the Golf to the appearance of a minute cephalopod, but in Cephaloidea the posterior
part of the dorsal surface is raised up into three transverse fringed lamellae. These animals are epizooic, i.e. they live attached to the outer surface of other organisms, but are not ectoparasitic for they ingest Intusoria, Rotifera and Diatoms. Most of the species occur on fresh-water crayfish and crabs in Chile, Madagascar, the Malay Archipelago and Australasia. Two Brazilian forms are known, one from the pulmonary chamber of the mollusc *Amphularia* and the other from water tortoises. The genus *Tennnocephala* is found in all the countries mentioned. The two others, *Craspedella* and *Actinodactyrella* are only known from Australia.

The epidermis offers an interesting transitional structure. It is still, as in Turbellaria, cellular, or rather syncytial without cell-boundaries, but in most species has lost its cilia and developed a thick cuticle as in Trematodes, pierced by the necks of subdermal gland-cells. These cells, however, still retain the Turbellarian character of secreting rhizoblasts and form thickly-grouped tracts. The mouth, which is placed near the anterior end, leads into a bulbous pharynx from which a short, broad digestive sac is given off. The excretory system is peculiar. Besides the ordinary flame cells, single large canaliculated cells may form the commencement of the tubules, composed of comparatively few cells with large nuclei. They open to the exterior by a pair of contractile sacs situated dorsally at the level of the mouth as in certain Trematoda. Each sac is the product of a single cell, and is said to contain several branches of "flames" or synchronously contractile cilia. The reproductive system recalls that of certain Rhadobranchs, whilst the nervous system has retained a more primitive condition. The brain, which is placed over the mouth, gives rise to six main longitudinal tracts interconnected by a subdermal network. A pair of eyes is placed above the brain.

Class and order *Tennnocephalidea*.—Platyelma in which the flattened body is produced into anterior or anterior and lateral tentacular processes and carries a ventral sucker. The epidermis is a syncytium covered by a thick cuticle. Cilia and rhizoblasts are present. Family I.: *Tennnocephalidae*: 4-12 anterior tentacles. Family II.: *Actinodactylidae*: Lateral tentacular processes.

**PLANCER, or PLANCHER** (O. Fr. *plancier*, or *planchier*, planking), in architecture, a term sometimes used in the same sense as a soffit, but more correctly applied to the soffit of the corona in a cornice.

**PLANCHE, JEAN BAPTISTE GUSTAVE** (1808–1857), French critic, was born in Paris on the 16th of February 1808. INTRO-duced by Alfred de Vigny to François Buluz, he began to write for the *Revue des deux mondes*, and continued to do so until 1840. He resumed his connexion with the journal in 1846 and contributed to it until his death in Paris on the 10th of September 1857. Gustave Planche was an altogether honest critic and refused to accept a place from Napoleon III. for fear of compromising his freedom. He was in early life a fervent admirer of George Sand, and he lavished praise on De Vigny. But he had nothing but scorn for Victor Hugo, whose earlier dramas he characterized as odes, those following _Le Roi s’amuse_ as anti-theses, and the later ones as nothing but spectacle. His critical papers were collected under the titles: *Portraits littéraires* (1836–1849); *Nouveaux portraits littéraires* (1854); and art criticisms, _Études sur l’œuvre française_ (1855).

See Ernest Montégu, in the *Revue des deux mondes* (June 1858); Hatzfeld and Meunier, *Les Critiques littéraires du XIXe siècle* (1891).

**PLANCHÉ, JAMES ROBINSON** (1796–1880), English dramatist and antiquary, was born in London on the 27th of February 1796, the son of a watchmaker of Huguenot descent. In 1810 he was articled to a bookseller. In 1818 his first dramatic piece, a burlesque entitled _Amoroso, King of Little Britain_, was produced at Drury Lane theatre. From this time onwards he made play-writing his principal work. In 1820–1821 he wrote ten pieces for the Adelphi theatre. In 1823 he designed the dresses for Charles Kemble’s revival of _King John_ at Covent Garden, and superintended its production. This was the first time that an historical drama had been “dressed” in the costume of the period. In 1828 he began writing regularly for Covent Garden theatre, and in 1830 was manager of the Adelphi. On Mme Vestris taking the Olympic theatre in 1831, Planché entered into an agreement with her to write a series of plays. The first of these, _Olympic Revels_, a burlesque, was given on the opening night of the theatre, the performance being given in correct classical costume. In 1843 his _Fair One with the Golden Locks_ was produced by Webster at the Haymarket. In 1847 Mme Vestris became manageress of the Lyceum theatre, and Planché was engaged as her leading author and designer, his principal success being the _Island of Jewels_ (1849). Subsequently he wrote for a number of other managers, his last dramatic piece being _King Christmas_ (1871), but he also wrote the songs for _Babyl and Bawm_ at Covent Garden (1872). In addition to his dramatic work Planché enjoyed a considerable reputation as an antiquary and heraldic student. He was a Fellow of the Society of Antiquaries, and aided in the foundation of the British Archaeological Association in 1843. In 1834 he published _The History of British Costumes_. In 1854 he was appointed Rouge Croix pursuivant of arms at the Heralds’ College, and in 1866 Somerset herald. In 1869, at the request of the War Office, he arranged the collection of armour at the Tower of London in chronological order. He died at Chelsea on the 30th of May 1880.

Planché’s _Recollections and Reflections_ were published in 1872.

**PLANCK, GOTTLIEB JAKOB** (1751–1833), German Protestant divine and historian, was born at Nürtlingen in Württemberg, where his father was a notary, on the 15th of November 1751. Educated for the Protestant ministry at Blaubeuren, Bebenhausen and Tübingen, he became _repmént* at Tübingen in 1774, preacher at Stuttgart in 1780, and professor of theology at Göttingen in 1784. At Tübingen he wrote _Das Tagebuch eines neuen Eheman* in 1781. In 1781 he published anonymously the first volume of his _Geschichte des protestantischen Lehrbegriffs_; the second, also anonymous, appearing in 1783, and it was completed in six volumes in 1800. It was followed by an extensive _Geschichte der christlich-kirchlichen Gesellschaftsverfassung in five volumes_ (1803–1809). Both are works of considerable importance, and are characterized by abundant learning. He died on the 31st of August 1833. His son Heinrich Ludwig Planck (1785–1831), also professor of theology at Göttingen, published _Bemerkungen über den ersten Brief an den Timotheus_ (1808) and _Abridg d. philos. Religionslehre_ (1821).
PLANCK, KARL CHRISTIAN (1810–1880), German philosopher, was born at Stuttgart on the 17th of January 1810. He studied at Tübingen, where he became doctor of philosophy in 1830 and Privatdozent in 1848. During this period the influence of Reiff led him to oppose the dominant Hegelianism of the time. In 1850–1851 he published his great book, Die Weltalter, in which he developed a complete original system of philosophy, based on the realistic view that thought should proceed from nature to the highest forms of existence in the spiritual life. Not only did Planck oppose the idealism of his confrères; his views were, in another aspect, directly antagonistic to the Darwinian theory of descent, which he specifically attacked in Wahrheit und Flachheit des Darwinismus (Nördlingen, 1872). The natural consequence of this individuality of opinion was that his books were practically disregarded, and Planck was deeply incensed. The ill success of Die Weltalter served him to new efforts, and he repeated his views in Kritik des Rechts (1852), Grundriss einer Wissenschaft der Natur (1864), Seele und Geist (1871), and numerous other books, which, however, met with no better fate. In the meantime he left Tübingen for Ulm, whence he came finally to the seminary of Maulbronn. He died on the 7th of June 1880 in an asylum after a short period of nervous prostration. After his death a summary of his work came into the hands of K. Köstlin (author of Aesthetics, 1869), who published it in 1881 under the title Testament eines Deutschen, Philosophie der Natur und der Menschheit. Planck’s views were elaborately developed, but his method of exposition told heavily against their acceptance. He regarded himself as the Messiah of the German people.

Beside the works above quoted, he wrote System des reinen Idealismus (1851); Anthropologie und Psychologie auf naturwissenschaftlicher Grundlage (1874); a political treatise, Bismarck: Süd- deutschland und der deutsche Nationalstaat (1872); and Logisches Causalgese and natürliche Zweckmäßigkeit (1874).

See Umfrid, Karl Planck, dessen Werke und Wirken (Tübingen, 1881); and Schmidt, “Das Lebensideal Karl Christian Plancks,” in the Vorträge der philosophischen Gesellschaft (Berlin, 1896).

PLANE. 1. In botany, the common name of a handsome tree known botanically as Platanus orientalis, a native of Greece and western Asia, a favourite shade-tree of the ancient Greeks and Romans, and introduced by the latter to south-west Europe. It

is one of the most successful trees in London and other large towns; the smooth face of the leaf is easily washed by rain; and the periodical peeling of the bark also serves to get rid of impurities. It is a large tree with widely spreading branches and alternate, palmately five-lobed leaves, resembling those of the sycamore in shape, but quite hairless and of a brighter green.

The bud in the leaf axil is protected during its development by the hollow base of the leaf-stalk, which lifts off like an extin-

guisher when the leaf falls in autumn. The minute, unisexual flowers are borne in dense pendulous heads, which contain either male or female flowers; the small one-seeded fruits are densely crowded in a ball, from which they gradually separate in drying, and are readily carried by the wind. The wood, which is hard and heavy, though not strong, is used in Persia and other coun-

tries for house construction and furniture. A variety of forms are known in cultivation, the commonest being the maple-leaved (acerifolia), the London plane, which has usually three-lobed leaves; var. laciniata has very deeply much divided leaves, and var. variegata, variegated foliage. Platanus occi-

dentalis, an allied species, is a native of the United States, being most abundant and growing to its largest size in the bottom lands of the basins of the lower Ohio and the Mississippi rivers. It was introduced into England early in the 16th century, and is occasion-

ally met with in western and central Europe. Professor C. S. Sargent (Silva of North America) refers to it as the most massive if not the tallest, deciduous-leaved tree of the North American forest; it is known in America as sycamore and buttonwood. It differs from P. orientalis in its less deeply lobed, more leathery pubescent leaves and in the usually solitary balls of fruit.

2. The name of a carpenter’s hand-tool, used for levelling and smoothing (Lat. planus, level) the surface of wood. The machine tool used for a similar purpose for metals is generally known as a planing-machine or planer.

PLANET (Gr. πλανήτης, a wanderer), in the ancient astronomy, one of seven heavenly bodies characterized by being in motion relative to the fixed stars, which last appeared immovable upon the celestial sphere. As thus defined the planets were the sun, the moon, Mercury, Venus, Mars, Jupiter and Saturn. In modern astronomy since Copernicus, the term is applied to any ope-

que body moving around the sun. Taken in its widest sense it applies to the satellites which are sometimes termed secondary planets. Each of these moves around a planet larger than itself, which it accompanies in its revolution round the sun. A planet not revolving round another is termed a primary planet.

The primary planets are classified as major and minor. The former are eight in number and, with the sun, form the principal members of the solar system, under which head their arrange-

ment is described. The earth on which we live is the third in the order of the major planets from the sun. With respect to the positions of their orbits relative to the earth, the other planets are distinguished as inferior and superior. The former, only two in number, comprise Mercury and Venus, which revolve between the earth and the sun. The superior planets are those whose orbits are outside that of the earth. The synodic revolution of an inferior planet is the time in which it performs a revolution relative to the line joining the earth and the sun. This is greater than its actual time of revolution. The phases or appearances presented by such a planet depend upon its configuration with respect to the earth and sun, and therefore go through their complete periods in a synodic revolution. At superior conjunc-

tion the illuminated hemisphere of the planet is presented to the earth so that it presents the form of a full moon. As it moves towards inferior conjunction, the lines from the planet to the sun and to the earth, or the angle sun-earth as seen from the planet, on which the phase depends, continually make a greater angle. At the time of greatest elongation this angle is 90°, and the planet appears one half illuminated, like the moon at first or last quarter. Then, as it approaches inferior conjunction, the visible portion of the disk assumes the crescent form, and while the circle bounding the disk continually increases owing to the approach of the planet to the earth, the crescent becomes thinner and thinner until, near inferior conjunction, the planet is no longer visible. After conjunction the phases occur in the reverse order of the preceding. The brilliance of these planets, as measured by the total amount of light we receive from it, goes through a similar cycle of change. The point of greatest brilliancy is between inferior conjunction and greatest elongation. In the case of Venus this phase occurs about three or four weeks before and after inferior conjunction.
In the figures given above are shown the relative orbits of the planets, the orbits of Mars, the Earth, Venus and Mercury (fig. 1) being drawn to a scale twenty times that of the outer ones—Neptune, Uranus, Saturn, Jupiter (fig. 2). The positions of the planets at ten-day intervals; their actual position on the 1st of January 1910 at noon, of their nodes and nearer apses, and the points when they are farthest distant north and south of the ecliptic, are also given.

The relative sizes of the planets are also given, orientated in their true axial position with regard to the ecliptic. The nearer planets (and also the Moon) are separately compared (fig. 3); and then shown (on a smaller scale) in comparison with the more distant ones (fig. 4). Finally scale diagrams of the distances of the orbits of the satellite-systems of Saturn, Uranus, Jupiter and Neptune are given (fig. 5).
The phases of a superior planet are less strongly marked, because the lines from the planet to the earth and sun never increase to a right angle. The result is that although the apparent disk of any of these planets may have marked features, it is always more than half illuminated. In the case of the other superior planets, from Jupiter outward, no variation in phase is perceptible even to telescopic vision. The entire disk always seems fully illuminated.

The most favourable time for viewing an inferior planet is near that of greatest brilliancy. As it recedes further from the earth, although a continually increasing proportion of its disk is illuminated by the sun, this advantage is neutralized by the diminution in its size produced by the increasing distance. When a superior planet is in opposition to the sun it rises at sunset and is visible all night. This is also the time when nearest the earth, and therefore when the circumstances are most favourable for observation.

The greater the distance of a planet from the sun the less is the speed with which it moves in its orbit. The orbit being larger, the time of its revolution is greater in a yet larger degree. An approximation to the general laws of speed in different planets is that the linear speed is inversely proportional to the square root of the mean distance. From this follows Kepler's third law, that the squares of the times of revolution are proportional to the cubes of the mean distances.

Notes on the Plate showing Planetary Spectra.

Only those lines and bands are mentioned which are peculiar to the planets; the Fraunhofer lines are therefore omitted.

It was once supposed that the planets were surrounded by comparatively dense atmospheres. The question whether such are the case, and, if so, what is the physical constitution of the atmospheres, is a difficult one, on which little light is thrown except by the spectroscopic analysis of the lines of these bodies. If any of these bodies is surrounded by a transparent atmosphere like that of the earth, the light which reaches us from the latter will have passed twice through this atmosphere. If the latter were materially different in its constitution from that of the earth, that fact would be made known by the spectrum showing absorption lines or bands different from those found in the solar spectrum as we observe it. If, however, the planetary atmosphere had the same composition as ours we should see only an intensification of the atmospheric lines, which might be imperceptible were the atmosphere rare.

Actual observation has thus far shown no well marked deviation in the spectra of any of the inner group of planets, Mercury, Venus and Mars, from the solar spectrum as we see it. It follows that the other planets may have much, if not transparent, be rare. The evidence in the cases of Venus and Mars is given in the articles on these planets. Taking the outer group of planets, it is found that the spectrum of Jupiter shows one or more very faint shaded bands not found in that of the sun. In Saturn these bands become more marked, and in Uranus and Neptune many more are seen. The spectra in question have been observed both optically and photographically by several observers, among whom Huggins, Vogel and Lowell have been most successful. It may be said, in a general way, that seven or eight well marked dark bands, as well as some fainter ones are observable in the spectra of the two outer planets. The general conclusion from this is that these planets are surrounded by deep and dense atmospheres, semi-transparent, of a constitution which is probably very different from that of the earth's atmosphere. But it has not, up to the present time, been found practicable to determine the chemical constitution of these appendages, except that hydrogen seems to be an important constituent. (See Planet.)

Intimately associated with this subject is the question of the conditions necessary to the permanence of an atmosphere round a planet. Dr Johnstone Stoney investigated these conditions, taking as the basis of his work the kinetic theory of gases (Trans. Roy. Dublin Soc., vol. iv. p. 303). On this theory every molecule of a gaseous mass is completely disconnected from every other and is in rapid motion, its velocity, which may amount to one or more thousand feet per second, depending on the temperature and on the atomic weight of the gas. At any temperature the velocities of individual molecules may now and then increase without any well-defined limit. If at the boundary of an atmosphere the velocity should exceed a certain limit fixed by the mass and force of gravity of the planet, molecules might fly away through space as independent bodies. The absence of hydrogen from the atmosphere of the earth, and of an atmosphere from the moon, may be thus explained. If the fundamental hypotheses of Dr Stoney's investigations are correct and complete, it would follow that neither the satellites and minor planets of the solar system nor Mercury can have any atmosphere. If the separate molecules thus flying away moved according to the laws which would govern an ordinary body, they would, after leaving their respective planets, move round the sun in independent orbits. The possibility is thus suggested that the matter producing the zodiacal light may be an agglomeration of gaseous molecules moving round the sun; but several questions respecting the intimate constitution of matter will have to be settled before any definite conclusions on this point can be reached. It is not to be assumed that a molecule would move through the ether without resistance as the minutest known body does, and there is probably a radical difference between the minutest particle of meteoric matter and the molecule of a gas. The relations of identity or difference between such finely-divided matter as smoke and atmospheric haze and a true gas have yet to be fully established, and until this is done a definite and satisfactory theory of the subject does not seem possible.

Since the radiation of heat by a planet is, with our present instruments, scarcely capable of detection and measurement, the temperature of these bodies can be estimated only from general physical laws. The laws governing the radiation of heat have been so developed during recent years that it is now possible to state with at least the general principle on which a conclusion as to the temperature of a planet may be reached. At the same time our knowledge of the conditions which prevail on other planets is so limited, especially as regards their atmospheres, that only more or less probable estimates of the temperature of their surfaces can even now be made. Summarily stated, some of the physical principles are these:—

1. A neutrally coloured body—understanding by that term...

Fig. 1. ORION NEBULA.—Typical of the spectrum of the gaseous nebulae; contains bright lines of nebulum, hydrogen and helium. (The helium lines are too faint to show in this reproduction.)

Fig. 2. RIGEL.—Typical of the helium star spectrum; contains, in addition to the helium series and so-called Orion lines, dark lines of hydrogen.

Fig. 3. SIRIUS.—The hydrogen type spectrum; contains dark hydrogen lines at their greatest strength and many fine metallic lines.

Fig. 4. PROCYON.—Transition or hydrogen-to-solar type spectrum. The hydrogen lines are weaker, the metallic lines stronger, than in Sirius.

Fig. 5. SUN.—Hydrogen absorption fainter, metallic lines stronger and more numerous.

Fig. 6. ARCTURUS.—Advanced solar type spectrum.

Fig. 7. BETELGEUSE.—Typical of the spectrum partaking of the nature of that of the sun and that of the long-period variable star exemplified in Fig. 8.

Fig. 8. MIRA CETI.—A spectrum typical of the long-period variable, containing bright hydrogen lines and dark bands or flutings which are sharply defined on the more refrangible edge. [Plate used in photographing this spectrum was not sensitive below $\lambda$7200, hence no light-action below that point.]
one which absorbs the same fraction of the thermal radiation falling upon it whatever the wave length of this radiation—exposed to the sun’s radiation in void space tends to assume a definite temperature, called the normal temperature, the degree of which depends upon the distance of the body from the sun. This is a result of Kirchhoff’s laws of radiation.

2. An atmosphere surrounding such a body, if at rest, will tend to assume a state of thermal equilibrium, in which the temperature will be the same at all heights.

3. If the atmosphere is kept in constant motion by an interchange between its higher and lower portions, the tendency is towards adiabatic equilibrium, in which the temperature diminishes at a constant rate with the height, until it may approach the absolute zero. The rate of diminution depends upon the intensity of gravity and the physical constants of the gases composing the atmosphere.

4. In the actual case of a planet surrounded by an atmosphere and exposed to the sun’s radiation, the actual rate of diminution of temperature with height above the surface of the planet lies between the extreme limits just defined, the rate varying widely with the conditions. The general tendency will be towards a condition in which the temperature at the base of the atmosphere is higher than the normal, while in the upper regions it is lower. The temperature of the surface of the planet on which the atmosphere rests is determined partly by the sun’s radiation and partly by the temperature of the air. What we should generally expect in the absence of any selective absorption by the air is that the temperature of the lower air would be higher than that of the material surface on which it rests. But this condition might be reversed by the effect of such absorption in either the air or the material of the planet.

something of this sort has been suspected in the case of Jupiter, which has several points of resemblance to the sun. The planets Uranus and Neptune which, but for their atmospheres, would approximate to the absolute zero in temperature, may be prevented from doing so by the dense atmosphere which the telescope shows around them.

A very elaborate investigation of the probable mean temperatures of the surfaces of the several planets has been made by J. H. Poynting, Phil. Trans. (vol. 2024, 1904).

**Tables of Planetary Elements and Constants.**

Table I. gives the elements determining the motions of each major planet, and Table II, certain numbers pertaining to its physical condition. For explanation of terms used see Orbit.

The elements are given for the epoch 1900, Jan., Greenwich mean time, except the mean longitudes, which are for 1910, Jan. o.

In interpreting or using the numbers it must be remembered that only the mean distances and mean daily motions can be regarded as well determined and invariable quantities. The other elements are subject to a secular variation, and all vary more or less from the action of the planets. In Table II, the reciprocal of the mass is given, the mass of the sun being unity. Some of these and other quantities are extremely uncertain. This is especially the case with the mass of Mercury, which the astronomical tables put at 1/10,000,000 that of the sun, while C. W. Bill has computed from an estimate of the probable density of the planet that it is probably less than 1/11,000,000. In the table we assume the round number 1/10,000,000. The volumes are derived from micro-metric measures of the diameters, which are more or less uncertain. From these and the mass follows the density of each planet. From this again is derived the intensity of gravity at the surface; this is also frequently uncertain. Finally the normal temperature is that which a black or neutral coloured body would assume when every part of it is equally exposed to the sun’s rays by a rapid revolution. As has already been intimated, the actual temperature may also depend upon the interior heat of the planet, which is an unknown quantity.

It would follow from these laws that the temperature of the superior planets diminishes rapidly with distance from the sun, and must therefore be far below that of the earth, unless they are surrounded by atmospheres of such height and density as to be practically opaque to the rays of heat, or unless they have no solid crust.

The resemblance of the spectra of Mars, Jupiter and Saturn to that of the sun leads to the conclusion that the atmospheres of these planets are transparent down to the reflecting surface of the body. The temperature of these surfaces must therefore be determined by Kirchhoff’s law, unless they resemble the sun in being entirely liquid or gaseous, or in having only solid nuclei surrounded by liquid matter in a condition of continual movement.

**PLANETS, MINOR.** The minor planets, commonly known as asteroids or planetoids, form a remarkable group of small planetary bodies, of which all the known members but three move between the orbits of Mars and Jupiter. Until recently they were all supposed to be contained within the region just mentioned; but the discovery of one, which at perihelion comes far within the orbit of Mars, and of two others, which at aphelion pass outside the orbit of Jupiter, shows that no well-defined limit can be set to the zone containing them. Before the existence of this group was known, the apparent vacancy in that region occupied by it, as indicated by the arrangement of the planets according to Döbe’s law, had excited remark and led to the belief that a planet would eventually be found there. Towards the...
end of the 18th century the conviction that such a planet existed was so strong that an association of astronomers was formed to search for it. The first discovery of the looked-for planet was not, however, made by any member of this association, but by Giuseppe Piazzi of Palermo. On the 1st of January 1801 he noted a small star in Taurus, which, two days later, had changed its place, thus showing it to be a planet. Shortly after Piazzi’s discovery the body was lost in the rays of the sun, and was not again seen until near the following opposition in 1801–1802. The orbit was then computed by C. F. Gauss, who found its mean distance from the sun to correspond with Bode’s law, thus giving rise to the impression that the gap in the system was filled up. The planet received the name Pallas.

On the 28th of March 1802 H. W. M. Olbers (1758–1840) discovered a second planet, which was found to move in an orbit a little larger than that of Ceres, but with a very large eccentricity and inclination. This received the name of Vesta. The existence of two planets where only one was expected led Olbers to his celebrated hypothesis that these bodies were fragments of a larger planet which had been shattered by an internal convulsion; and he proposed that search should be made near the common node of the two orbits to see whether other fragments could be found. Within the next few years two other planets were discovered, bringing the number to four. No others were found for more than a generation; then on the 8th of December 1845, a fifth, Astrea, was discovered by K. L. Hencke of Driesen. The same observer added a sixth in 1847. Two more were found by J. R. Hind of London during the same year, and from that time discovery has gone on at an increasing rate, until the number now known is more than six hundred and is growing at the rate of thirty or more annually.

Up to 1850 discoveries of these bodies were made by skilful search with the telescope and the eye. Among the most successful discoverers were Johann Palisa of Vienna, C. H. F. Peters (1815–1890) of Clinton, New York, and James Craig Watson (1822–1890) of Edinburgh. After 1850 many of the observations were made almost entirely by photography. When a picture of the stars is taken with a telescope moved by clockwork, so as to follow the stellar sphere in its apparent diurnal rotation, the stars appear on the plates as minute dots. But if the image of a planet is imprinted on the plate it will generally appear as a short line, owing to its motion relative to the stars. Any such body can therefore be detected on the plate by careful examination much more expeditiously than by the old method of visual search. The number now known is so great that it is a question whether they can be much longer individually followed up so as to keep the run of their movements.

Among the distinctive features of the planets of this group one is their small size. None exists which approaches either Mercury or the moon in dimensions. The two largest, Ceres and Juno, present, at opposition a visible disk about 1' in diameter, corresponding to about 400 miles. The successively discovered ones naturally have, in the general average, been smaller and smaller. Appearing only as points of light, even in the most powerful telescopes, nothing like a measure of their size is possible. It can only be inferred from their apparent magnitude that the diameters of those now known may range from fifteen or twenty miles upwards to three or four hundred, the great majority being near the lower limit. There is yet no sign of a limit to their number or minuteness. From the increasing rate at which new ones approaching the limit of visibility are being discovered, it seems probable that below this limit the number of unknown ones is simply countless; and it may well be that, could samples of the entire group be observed, they would include bodies as small as those which form the meteors which so frequently strike our atmosphere. Such being the case, the question may arise whether the total mass of the group may be so great that its action on the major planets affects its detection. The computations of the probable mass of those known, based upon their probable diameter as concluded from the light which they reflect, have led to the result that their combined action must be very minute. But it may well be a question whether the total mass of the countless unknown planets may not exceed that of the known. The best answer that can be made to this question is that, unless the smaller members of the group are almost perfectly black, a number great enough to produce any observable effect by their attraction would be visible as a faintly illuminated band in the sky. Such a band is occasionally visible to very keen eyes; but the observations on it are, up to the present time, so few and uncertain that nothing can positively be said on the subject. On the other hand, the faint "Gegenschein" opposite the sun is sometimes regarded as the manifestation of this supposed band of light, due to the increased reflection of the sun’s light when it is back perpendicularly (see Zodiacal Light). But this supposition, though it may be well founded, does not seem to fit with all the facts. All that can be said is that, while it is possible that the light reflected from the entire group may reach the extreme limit of visibility, it seems scarcely possible that the mass can be such as to produce any measurable effect by its attraction.

Another feature of the group is the generally large inclinations and eccentricities of the orbits. Comparatively few of these are either nearly circular or near any common plane. Considering the relations statistically, the best conception of the distribution of the planes of the orbits thus far may be gained by considering the position of their poles on the celestial sphere. The pole of each orbit is defined as the point in which an axis perpendicular to the plane intersects the celestial sphere. When the poles are marked as points on this sphere it is found that they tend to group themselves around a certain position, not far from the pole of the invariant plane of the planetary system, which again is very near that of the orbit of Jupiter. This statistical result of observation is also inferred from theory, which shows that the pole of each orbit revolves around a point near the pole of the invariant plane with an angular motion varying with the mean distance of the body. This would result from the periodic attraction of the planets around that of Jupiter, the latter being the centre of position of the whole group. From this it would follow that, if we referred the planes of the orbit to that of Jupiter, the nodes upon the orbit of that planet should also be uniformly scattered. Examination, however, shows a tendency of the nodes to crowd into two nearly opposite regions, in longitudes of about 180° and 330°. But it is difficult to regard this as anything but the result of accident, because as the nodes move along at unequal rates they must eventually scatter, and must have been scattered in past ages. In other words it does not seem that any other than a uniform distribution can be a permanent feature of the system.

A similar law holds true of the eccentricities and the perihelia. These may both be defined by the position of the centre of the orbit relative to the sun. If abe be the mean distance and e the eccentricity of an orbit, the geometry of the ellipse shows that the centre of the orbit is situated at the distance ae from the sun, in the direction of the apsillum of the body. When the centres of the orbits are laid down on a diagram it is found that they are not scattered equally around the sun but around a pole lying in the direction of the centre of Jupiter. The direction governing these may be seen from fig. 1. Here S represents the position of the sun, and J that of the centre of the orbit of Jupiter. The direction JS produced is that of the perihelion of Jupiter, which is now near longitude 12°. As the perihelion moves by its secular variation, the line SJ revolves around S. Theory then shows that for every asteroid there will be a certain point A near the line SJ and moving with it. Let C be the actual position of the centre of the planetoid. Theory shows that C is in that same line and SD CA is the direction shown by the arrow, the line eccentricity ae being represented by the line SC. It follows that e will be at a minimum when AC passes through S, and at a maximum when in the opposite direction. The position of A is also the same as that of the planets of this group, except for the case of Different planoids, but is generally about two-thirds of the way from S to J. The lines AC for different bodies are at any time scattered miscellaneous around the region A as a centre. AC may be called the constant of eccentricity of the planetoid, while SC represents its actual but varying eccentricity.
Grouping of the Planetoids.—A curious feature of these bodies is that when they are classified according to their distances from the sun a tendency is seen to cluster into groups. Since the mean distance and mean motion of each planet is connected by Kepler’s third law, it follows that this grouping may also be described as a tendency toward certain times of revolution or certain values of the mean motion around the sun. This feature was first noticed by D. Kirkwood in 1870, but at that time the number of planetoids known was not sufficient to bring out its true nature. The seeming fact pointed out by Kirkwood was that, when these bodies are arranged in the order of their mean motions, there are found to be gaps in the series at those points where the mean motion is commensurable with that of Jupiter; that is to say, there seem to be no mean daily motions near the values 598°, 748° and 988°, which are respectively 2, 2 2/3 and 3 times that of Jupiter. Such mean motions are nearly commensurable with that of Jupiter, and it is shown in celestial mechanics that when they exist the perturbations of the planet by Jupiter will be very large. It was therefore supposed that if the commensurability should be exact the orbit of the planet would be unstable. But it is now known that such is not the case, and that the only effect of even an exact commensurability would be a libration of long period in the mean motion of the planetoid. The gaps cannot therefore be accounted for on what seemed to be the plausible supposition that the bodies required to fill these gaps originally existed but were thrown out of their orbits by the action of Jupiter. The fact can now be more precisely stated by saying that we have not so much a broken series as a tendency to an accumulation of orbits between the points of commensurability. The law in question can be most readily shown in a graphical form. In fig. 2 the horizontal line represents distances from the sun, increasing toward the left, of which certain equidistant numerical values are given below the line. Points on the line corresponding to each 0.01 of the distances are then taken, and at each point a perpendicular line of dots is drawn, of which the number is equal to that of the planetoids having this mean distance, no account being taken of fractions less than 0.01. The accumulations between the points of close commensurability with the mean motion of Jupiter may be seen by inspection. For example, at the point 2-59 the mean motion is three times that of Jupiter; at the point 2-81 twice the mean motion is equal to five times that of Jupiter; at 3-24 the mean motion is twice that of Jupiter. It will be seen that there is a strong tendency toward grouping near the values 2-75, and a lesser tendency toward 3-1 and 2-4. It is probable that the grouping had its origin in the original formation of these bodies and may be plausibly attributed to the formation of three or more separate rings which were broken up to form the group.

Continuing the question beyond these large collections, it will be seen that between the values 3-22 and 3-33 there are no orbits at all. Then between 3-3 and 3-5 there are nine orbits. The space between 3-5 and 3-9 is thus far a complete blank; then there are three orbits between 3-90 and 3-95, not shown in the diagram.

A group of great interest, of which only three members are yet known, was discovered during the years 1906-1907. The mean distance of each member of this group, and therefore its time of revolution, is so near that of Jupiter that the relations of the respective orbits are yet unknown. The case thus offered for study is quite unique in the solar system, but its exact nature cannot be determined until several more years of observation are available.

Several planetoids of much interest are situated without the limits of the groups shown in the figure. Eros is so near the sun, and its orbit is so eccentric, that at perihelion it is only about 0·16 outside the orbit of the earth. On those rare occasions when the earth is passing the perihelion point of the orbit at nearly the same time with Eros itself, the parallax of the latter will be nearly six times that of the sun. Measurements of parallax made at these times will therefore afford a more precise value of the solar parallax than can be obtained by any other purely geometrical measurement. An approach almost as close as the nearest geometrically possible one occurred during the winter of 1893-1894. Unfortunately the existence of the planet was then unknown, but after the actual discovery it was found that during this opposition its image imprinted itself a number of times upon the photographs of the heavens made by the Harvard Observatory. The positions thus discovered have been extremely useful in determining the elements of the orbit. The next near approach occurred in the winter of 1900-1901, when the planet approached within 0·32 of the earth. A combined effort was made by a number of observatories at this time to determine the parallax, both by micrometric measures and by photography. Owing to the great number of stars with which the planet had to be compared, and the labour of determining their positions and reducing the observations, only some fragmentary results of this work are now available. These are mentioned in the article PARALLAX. So far as can yet be seen, no other approach so near as this will take place until January 1931.

A few of the minor planets are of such special interest that some pains will doubtless be taken to determine their orbits and continue observations upon them at every available opposition. To this class belong those of which the orbits are so eccentric that they either pass near that of Jupiter or approach near that of the earth. With most of the others little more can be done than to compute their elements with a view of subsequently identifying the object when desired. Unless followed up at several oppositions after discovery, the planet is liable to be quite lost. Of those discovered before 1890 about fifteen have not again been found, so that if discovered, as they doubtless will be, identification will be difficult.

The system of nomenclature of these bodies is not free from difficulty. When discoveries began to go on at a rapid rate, the system was introduced of assigning to each a number, in the order of its discovery, and using as its symbol its number enclosed in a circle. Thus Ceres was designated by the symbol C; Pallas by γ, &c., in regular order. This system has been continued to the present time. When photography was applied to the search it was frequently doubtful whether the planet of which the image was detected on the plates was or was not previously known. This led to the use of capital letters in alphabetical order as a temporary designation. When the alphabet was exhausted a second letter was added. Thus there are planetoids temporarily designated as A, B, &c., and AB, AC, &c. The practice of applying a name to be selected by the discoverer has also been continued to the present time. Originally the names were selected from those of the gods or goddesses of classical mythology, but these have been so far exhausted that the name is now left to the discretion of the person selecting it. At present it is customary to use both the number and the name, the former being necessary to the ready finding of the planetoid in a list, while the name serves for more certain identification.

(S. N.)

PLANK, a flat piece of timber, sawn and planed; it is technically distinguished from a “board” by its greater thickness, and should measure from 2 to 4 in. in thickness and from 10 to 11 in.
PLANKTON

in width. The word comes through the Fr. planche (from post-
Augustan, Lat. planca, a nasallad adaption probably of Gr. xiphos, a flat stone). The use of the
word "plank" in the sense of an article in a political programme
is of American origin and is due to the use of "platform" for
the programme itself.

PLANKTON, a name invented by Professor Victor Hensen
for the drifting population of the sea. This is a convenient
heading under which to discuss not only plankton proper, but
the benthos, or crawling population of the sea-bottom. Scientific
investigation of these subjects dates from the reports of the
"Challenger" expedition, which, despite its many successors,
still stands out as the most important of the oceanographic
expeditions, alike in the work achieved, the distance traversed,
the time occupied, and the money devoted to the publication of
the results. It laid the foundation of our knowledge of the
physics and chemistry of ocean water, of oceanic and atmospheric
currents, of the contour of the sea-bottom, and of the main
features of distribution of deep-sea life. Later work has con-
firmed and expanded, but not revoked, the conclusions thus
attained. But, in spite of this and of several subsequent
expeditions, it cannot be pretended that we are in a position
to formulate general canons of marine distribution other than
of the most tentative character. Two fallacies underlie many
attempts to define distributional oceanic areas for special groups;
the one, that such areas can be made to bear some relation to
existing geographical or even national divisions; the other, that
what is true for one group of the animal kingdom must hold
good equally for another. It is necessary at the outset to divest
oneself of these errors; oceanic conditions depend only very
indirectly upon the distribution of the land, and strongly swim-
ming or freely floating animals are not to be confined by the
same factors as determine the distribution of sessile forms, whose
range is governed by a variety of circumstances.

As Wyville Thomson pointed out long ago, there is but one
ocean. This surrounds the southern half of the globe, and has
two large gulfs generally called the Atlantic and Pacific Oceans,
which meet through narrow channels in the small Arctic Ocean,
and a half gulf, the Indian Ocean. The Atlantic and Pacific
exhibit a striking homology of atmospheric pressure and of
prevailing wind and current; the Indian, to a great extent,
represents the southern half of a larger one, but this resemblance
is modified by the neighbourhood of vast land masses.
The prevalent winds, dependent on the fairly constant distribution
of atmospheric pressure over the great oceans, are the most
important determinant of currents. As at most points in the
ocean the temperature, salinity and chemical composition of
the water are mainly determined by the currents—that is, by
the time of year in which the water came—it is obvious
that a study of currents must precede any general view of the
distribution of marine forms.

Regard must be had not merely to the superficial currents
indicated in fig. 1, but also to the movements of the deeper layer.
Ice melting at the poles, together with polar precipitation of hail,
snow and rain, yields large quantities of water of low salinity
and very low temperature; this water sinks under the warmer
saltier surface water drifted from lower latitudes, and, creeping
slowly north and south from the poles, covers the bottom of all
the great open oceans at very uniformly low temperatures (in
some cases as low as 30° F.). Between surface and bottom the
temperature gradually decreases (except where affected by local
circumstances), and in the middle layers the existence of slow
currents is suspected. The cold bottom water wells up to the
surface in certain areas, replacing the surface water drained
away by currents, notably to the westward of the great land
masses. Ocean water is remarkably uniform as regards its
contained salts and gases, and it does not seem likely that we
can look to these to explain the facts of distribution. In its
temperature, on the contrary, there is enormous variation.
While the bottom water of the ocean is very cold, and the mid-
water of a more or less intermediate temperature, the surface
water, according as it has drifted from the equator polewards
or in the reverse direction, has a mean annual temperature
somewhere between 84° and 30° F., losing or gaining heat on its
way. In the case of narrow or "closed" seas, and near land
masses, sea-water does not exhibit that uniformity of composition
which characterizes the open ocean; but even in such cases the
temperature is largely influenced by adjacent currents, and,
though less obviously than in the open ocean, seems to be a very
important agent in distribution.

The fauna of the sea is divisible into the plankton, the swim-
moving or drifting fauna which never rests on the bottom (generally
taken now to include E. Haeckel's nekton, the strong swimmers,
such as fish and cephalopods), and the benthos, which is fixed
to or crawls upon the bottom. These groups require a further
subdivision according to depth—the more necessarily since, to
some zoologists, any water over 100 fathoms is "deep" or even
"abyssal." It is simplest to begin with the benthos. From

3. The Equatorial (also 2nd Pacific and Indian).
4. Gulf Stream proper (Japan Stream).
5. Brazil Current (Australian Current).
7. Labrador Current (Kamchatka Current).
8. Falkland Current.
9. North Atlantic Drift, generally called Gulf Stream (North Pacific
Drift).
10. South Atlantic Drift, ill defined (South Pacific Drift).
13. Peru Current.
14. Antarctic Circumpolar Drift, 7th, its northerly branches on
the west sides of Africa and South America.

The shore seaways we may distinguish several zones. Even
the tidal zone, between high and low water-mark, is subdivisible
by its fauna and flora. There generally follows on this a very
gentle slope to the depth of about 100 fathoms, locally sub-
divisible into many lesser zones. It has been termed the
continental shelf or littoral zone, not very appropriately, since
it occurs round many oceanic islands, and even away from any
land. In this zone, if near land, fall to the bottom the heavy
materials produced by land waste and river drainage. The
fauna of this zone, generally very well characterized, may be
distinguished as the *epibenthos*. As with the shallowest or tidal zone, its nature varies much more according to latitude and the character of the coast than the deeper zones. Everywhere, however, the epibenthic fauna is exposed to certain definite environmental conditions, as compared with a deeper fauna: namely, a high or fairly high temperature (except near the poles); a fairly good light, with its important consequence, a vegetable basis of food supply; tide and current to distribute the larvae to a suitable habitat, which the varied nature of the bottom near land is likely to furnish. Passing farther seawards, we find a steeper slope to about the 500-fathom line, the so-called continental slope. In this zone the environment is absolutely different. The water, no longer subject to seasonal variations of temperature, or to direct sunlight, is cold, and of a nearly uniform annual temperature (300 fathoms, \(44.7\)° F.). Light has disappeared from all but the shallower part, and with it plant life; tide and current are no longer felt. To the latter fact is due, however, a great part of the food supply, which maintains in this zone an abundant fauna: a great quantity of organic matter, brought down by river action, produced by disintegrated sea-weed, and due to the death of surface organisms, together with the finer clayey materials of land waste, settles to the bottom in quiet water, near the 100-fathom contour, thus making the *mud-line* the richest feeding-ground in the ocean (Murray). The mud-line is the real upper limit of this zone; it typically begins at about 100 fathoms, but may begin at 5 to 20 fathoms in deep sheltered firths, or be pushed down to 500 fathoms where currents are strong. The fauna of this zone may be termed the *mesobenthos*; it is not so abundant, nor so sharply characterized, as the epibenthos, and yet is sufficiently distinct to deserve at any rate a provisional name. Another difference of condition between epibenthos and mesobenthos is the pressure of the water; at a depth of 500 fathoms this is, roughly speaking, half a ton to the square inch. It is very doubtful whether this enormous pressure makes the slightest difference to marine invertebrates, the tissues of which are uniformly permeated by fluids, so that the pressure is uniform in every direction; but animals with free gases naturally require time to adjust the gas-pressure when altering their levels. As regards the penetration of light, assimilative rays useful to plant life probably do not reach beyond 150 fathoms. Photographic rays have been detected as low as 220 fathoms, and if any light penetrate beyond this depth, it will consist only of blue, violet and ultra-violet rays; it has been suggested that the red colour prevalent in many deep-sea animals may be a screen from these hurtful rays. Below the 500-fathom line the ocean bottom exhibits almost uniform conditions everywhere, varied only by the character of the bottom deposit and the amount of food supply. In this zone, which extends from about 500 fathoms to the greatest depths (which may in some cases exceed 5000 fathoms, or more than 30 m.), the temperature at any given point is uniform throughout the year, and is always very low: the mean at 2200 fathoms is 35.2° F.; at greater depths and in special circumstances less than 30° F. has been recorded. The darkness is probably absolute; for food the animals are dependent upon each other and upon the incessant rain of dead plankton from higher levels; the pressure may be anything between half and five tons per square inch. To the fauna which lives in these remarkable circumstances the name *hypobenthos* may be applied.

That each of the three benthic groups is well characterized by a special fauna is shown by the following table, out of the total numbers of species captured by the "Challenger" at seventy stations in these three zones:

<table>
<thead>
<tr>
<th>Species confined to this Zone.</th>
<th>Species occurring in other Zones.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Epibenthos.</td>
<td>91 %</td>
</tr>
<tr>
<td>Mesobenthos .</td>
<td>74 .</td>
</tr>
<tr>
<td>Hypobenthos</td>
<td>61 .</td>
</tr>
</tbody>
</table>

Out of the 25 % of its species which the mesobenthos shares with other zones, 93 % occur also in the epibenthos, about 40 % in the hypobenthos; the mesobenthos, therefore, on these figures, may be taken to consist of 74 % of peculiar species, 15 % shared with the epibenthos, 10 % with the hypobenthos. Speaking of the benthos as a whole, it may be said that the following is the rule: the number of species of each of the three groups increases with increasing depth; animal life also tends to diminish with increasing distance from land; this may be partly due to the greater food supply near land, partly to the fact that population is obviously thinned on the advancing fringe of a migration.

The plankton can be divided into at least two groups: the fauna to which light and warmth are more or less necessary, which feeds either upon plants or upon organisms nearly dependent upon plant life, may be termed the *epipelagik*. This fauna is capable of a good deal of vertical movement upwards and downwards; the causes of which are still obscure, but most of its members seem rarely to descend lower than about 100 fathoms. Below this depth the fauna may be called the *mesopelagik*. In every area this appears to have its peculiar species, but the careful study by opening and closing tow-net samples of the distribution of the mesopelagik is of so recent a growth that no statistics, such as we have of the benthos, are available. It is now generally admitted that the mesopelagik extends to the lowest depths (e.g. 2750 to 2402 fathoms, Valdivia); but the number of specimens decreases rapidly after 200 fathoms, and below 1000 fathoms very little is captured. The conditions of light, temperature, pressure, &c., are practically those of the corresponding depths of the benthos; as regards the food, however, the mesopelagik can only depend upon intercepting dead organisms which are falling from higher horizons, or on capture of many pelagic organisms. It is possible, therefore, that the plankton immediately over the bottom may prove to be sufficiently distinct to be separately classed as *hypipelagik*.

The main subdivisions of the marine fauna having thus been briefly sketched, it is advisable to consider them in somewhat more detail. The *epibenthos* is obviously that fauna which, to which, except in polar regions, light and warmth are necessary; and the absence of these at greater depths is
probably the chief barrier to its vertical extension; the food supply is sufficiently plentiful in, at any rate, the upper parts of the mesobenthic zone to present no obvious barrier. The chemical constitution of the water (except to animals in brackish water near river mouths) and the pressure appear to exert little or no influence; and only those species which attach themselves to clean hard substances would be repelled by the mud-line.

The chief barrier to a horizontal extension of the epibenthos is undoubtedly temperature. As an example of its distribution may be taken the Gastropod and Lamellibranch Molluscs, as groups of which the distribution has been studied for many years by specialists. The shallow-water species fall into provinces (compare Cooke, *Comb. Nat. Hist.* vol. 5, *Molluscs,* ch. xii.), and a comparison of figs. 1 and 3 shows at once the profound influence upon them of the great currents. Taking the Atlantic Ocean, we find the Arctic species, tempted southwards by the cold Labrador Current, repelled northwards by the warm North Atlantic Drift. The Boreal or sub-Arctic species, many of which are identical on both sides of the ocean (2 and 2', fig. 3), lie much farther southwards on the west than on the east side, from the same causes. The warm-water molluscs of West Africa (5) are cut off from those of the east side (7) by the cold water from the great easterly Antarctic Drift, which impinges on the Cape, giving it a special fauna (6). On the South American coasts the tropical and temperate fauna reach respectively to 28° S. and 45° S. on the east coast, owing to the warm Brazil Current; but the corresponding groups on the west coast only to 5° S. and 37° S., being kept back by cold upwelling and Humboldt's Current. This influence is visible in individual species as well as in the facies of a fauna: *Patapua lapillus,* a temperate form, reaches on the east side of the Pacific to 24° N. and on the East Atlantic to 32° N.; but on the West Pacific only to 41° N. and the West Atlantic to 42° N., being repelled by the Japan stream (and other warm currents of the south-west monsoon) and Gulf Stream respectively.

But while some species may be confined to a bay, others to a province, others to an ocean, there are cosmopolitan species which either vertical or horizontal barriers, or both, fail to restrain. In relation to temperature the wide-ranging species are termed *eurythermal,* the limited, *stenothermal* (Moebius); the terms are useful to record a fact, but are not explanatory. It seems to be the case that to every organism is assigned a minimum temperature below which it dies, a maximum temperature above which it dies, and an optimum temperature at which it thrives best; but these have to be studied separately for every species. Similarly, in regard to depth, species have been classed as *eurybathic* and *stenobathic,* but, since increased depth practically means diminished temperature, these are probably merely expressions of the same fact in another form. That an Arctic shallow-water species should stretch to considerable depths is not surprising, but it is remarkable to find such forms as, for example, *Venus mesodesma* on a New Zealand beach at 55°F. and in 1000 fathoms at 37° off Tristan d'Acunha. The provinces of zoological distribution, like the geographical divisions of mankind, must be taken merely to indicate the facies of a well-characterized fauna, not to imply the restriction of all its inhabitants to that area.

In considering the effect of temperature (and this applies to plankton as well as to benthos down to 100 fathoms), attention must be directed not only to the question of general warmth or cold as expressed by the mean annual temperature, but also to the range between the annual extremes: these ranges of variation have been carefully mapped by Sir J. Murray (*Geog. Journ.* xii. 113; compare ibid. xiv. 34). Still more important to the death-rate than these is the suddenness with which such variations occur: many animals are known to endure great extremes of heat and cold if exposed to them gradually, but to succumb to rapid alterations of temperature. Hence the frontier districts (*Mischgebiete*) between opposing currents are characterized by a heavy death-rate, and constitute marked barriers. A conspicuous instance of such a barrier in distribution is afforded at the Cape. The warm Mozambique Current, with a south-westerly direction off Natal, meets a north-east branch of the cold Antarctic Drift, and is beaten back eastwards: a result of the constant warring of these hot and cold currents is a high range of sudden temperature variation. Hence the Cape fauna
consists mainly of only such species from neighbouring provinces as can endure high sudden variations; and the district is practically impassable. For example, nineteen species of Echinoids are known from the Cape district. Of these twelve are peculiar to the Indo-Pacific province, which stretches from East Africa to the Sandwich Islands and from Japan to Australia; two species are Southern Ocean forms, all but confined to south of 40° S.; four species are peculiar to the Atlantic Ocean: of these eighteen not one gets past the Cape into the next province; the nineteenth is practically a cosmopolitan (A. Agassiz, "Challenger" Reports; "Echinidea"; compare also C. Chun, Aus den Tiefen des Welmeeres, pp. 137, 158).

Among the barriers to the horizontal extension of epibenthos must be mentioned a wide deep ocean. The Indo-Pacific fauna ranges from East Africa to about 108° W., stepping from island to island over the Pacific; but this continuity is then broken by 37 degrees of longitude and more than 2000 fathoms of water, and such sessile species as are most Mollusca (cf. fig. 3) are unable to reach the American coast. This is presumably due to the fact that the planktonic larvae of epibenthic adults must settle on a suitable bottom within a certain period or die. In spite of the direct set of the currents from Florida to the British Isles, the epibenthos of the two is absolutely dissimilar; the similarity of the two Boreal provinces (3 and 4, fig. 3) is to be assigned to a former continuity by way of Greenland, Iceland and Faeroe; a similar continuity, still unbroken, is exhibited by the Aleutian province on both sides of the Pacific. Though larvae cannot cross wide oceans, adults may no doubt traverse great stretches occasionally on floating timber, &c.

This barrier by distance may be instanced in another way. In the Arctic regions land masses are continuous or contiguous, and there are many circumpolar species, as, for example, *Rhyynchonella psittacea*; towards the South Pole the southern continent is almost ice-bound, and the available land consists only of the tips of the continents and of the few oceanic Islands. Hence few if any littoral species are circumpolar. An example, not a single littoral Ophiurid surrounds the South Pole, but five or six species are circumpolar in the northern hemisphere.

Taking next the *mesobenthos* and *hypobenthos*, living at depths where temperature is constant and current practically negligible, there appears theoretically to be no reason why an organism which can thrive at 500 fathoms should not have a world-wide range over the bottom of all oceans. Yet this is not often, although occasionally, known to be the case; and although perhaps, speaking generally, hypobenthic species have wider ranges than epibenthic, still they also seem to be limited. It must, however, be remembered that the ocean is large, deep hauls of trawl or dredge few, and individuals at great depths scarce, so that too much stress must not be laid on this point. The "Challenger" results seem to allow of at least one generalization—the deeper the fauna, the wider its range. This is shown by the following table of the "Challenger" benthos: the first column gives the number of benthos species captured at depths indicated in fathoms by the second column; the percentage of these species which is known to have been captured between the tropics, as well as south and north of the tropics, is shown in the third column:

We can only guess at the causes of the apparently limited range of many deep-sea types. (a) One of these is probably the limited food supply: presumably, as with a land fauna, there are as many mouths in a given area as it will support, and an equilibrium of species is maintained which will at least hinder the extension of any one. For food the bulk of the deep-water fauna is dependent upon the rain of dead organisms falling from higher levels, these, slowly disintegrating (probably under chemical, not bacterial, action), seem to form with the bottom deposit a kind of nitrogenous ooze, through which many deep-sea organisms slowly swallow their way, as an earthworm goes through earth extracting nutrition. (b) Another hindrance to the extension of many deep-sea species is that they are *holobenthic*, that is, do not pass through a free-swimming larval stage; the means of dispersal is therefore regulated by the animal's own power of locomotion. Generally speaking, as might be expected, the freely-moving hypobenthos, fish and crustacea, have the widest ranges, and even these are not helped by currents, as are epibenthic or planktonic forms. The larval history of deep-sea water forms is, however, unfortunately obscure. (c) Local extension of area of a species being at best difficult in deep water for non-swimmers, the place and date of their first migration must be taken into account; forms which have comparatively recently adopted deep-water life cannot be expected to have spread far from their original centre. As regards this point, in the first place, it is with migration, not with local evolution, that we have to deal: no classes and orders, only a few families and genera, rarely sub-orders, are peculiar to the hypobenthos; the deep members of each group consist for the most part of widely separated genera, the species do not grade into each other, but are often similar to the case in the epibenthos; and even those families which have practically produced these species and genera under the uniformity of their present environment. This migration downwards from the mud-line has no doubt occurred all over the world, notably in the Southern Ocean, if we may judge by the richness of the deep-water fauna there to-day; probably also largely in Arctic and sub-Arctic regions, less so in tropical and temperate zones. As to the date of migration, the following fact seems to show that it is of comparatively recent origin, and is indeed still in progress: taking the "Challenger" species from the epibenthos, from the mesobenthos, and then from zones of 500 fathoms down to 2400, each zone shares a larger percentage of species with the zone above it than with that below it (except in one case where they are nearly equal). But it is not to be supposed that all our present-day deep-water forms began their migration simultaneously, and we can say with fair certainty that migration to deep water did not begin before the close of the Mesozoic epoch. Had it begun earlier, we should find typical Mesozoic and even older forms, or their congener, at great depths: so far is this from being the case that the most venerable animals of to-day—*Linguina, Amphioxus, Limulus, 75% of Crinoids, 90% of Brachiopoda, &c.—are epibenthic or mesobenthic. On the other hand, it is extremely likely that the Cretaceous genera are the most ancient. The hexactinellid sponges are known to have lived in quite shallow water at the date of deposition of the Inferior Oolite; to-day none occur at a less depth than 95 fathoms; and as only two genera are known from the shallow Tertiary deposits, it would seem that the migration began about Cretaceous times ("Challenger" Reports; "Hexactinellida," F. E. Schulze). In 1885 (A. Agassiz, "Challenger" Reports; "Echinoidea") 105 living genera of Echinoidea were admitted; of these 23% were known from Cretaceous but not from Tertiary deposits, 35% from Tertiary but not Cretaceous, and 40% as Recent only. The species of Cretaceous genera constituted only 29% of the epibenthic Echinoids, 44% of the mesobenthic, and no less than 55% of the hypobenthic. These species of Cretaceous genera were distributed fairly evenly over all three zones, but 73% of the species of Tertiary genera and 55% of the Recent forms were confined to the epibenthos. As out of the twenty-five living genera known from the Cretaceous only seven are known also from Jurassic deposits, it is obvious that the close relationship between Cretaceous and hypobenthos, rather than between any other geological and bathymetric horizons. Other instances, such as that of the Eryonidae, seem to point to similar conclusions.

Excepting the essential air-breathers, practically every phylum and class and most orders are represented in the benthos. The
epibenthos of warm seas appears to be especially wealthy in such forms as secrete heavy calcareous skeletons; but in colder water, among the epibenthos of polar or sub-polar regions, and the hypobenthos everywhere in open oceans, the predominant forms are those which exhibit little or no calcareous secretion: even the apparent exceptions, Madreporaria and Echinodermata from great depths, tend to develop lighter skeletons than their warm-water congeners. The following table will serve to illustrate this point, and to give an idea of the composition of the epibenthos of cold and warm seas and of the hypobenthos: the figures are the percentages of total species captured in each locality by H.M.S. "Challenger," the balance being made up by few specimens in scattered groups:

While the Madreporaria represent only 33% of the species at the tropical station, it must be remembered that they probably made up 80% or more of the weight.

The epibenthos is dependent either directly or proximately upon light, warmth and the presence of plant life. The wealth of minute organisms near the surface is inconceivable:

**Epibenthos.**

to those who have not seen the working of a two-net: it may be gauged by the fact that a single species is sometimes present in such quantities as to colour the sea over an appreciable area, and by the estimate that the skeletons of epibenthon from a square mile of tropical ocean a hundred fathoms deep would yield 16 tons of lime. In the tropics the wealth of species, and towards the poles the number of individuals of comparatively few species, are characteristic of the latitudes. In temperate and tropical regions there is a great difference between the epibenthon near land and that far out at sea: the former is termed neritic; it extends, roughly speaking, at least as far out as the mud-line, and is characterized by the predominance of what may be termed hemibenthic forms, that is, benthic forms with a planktonic larval stage (Decapoda, Polyplacidae, &c.), or with a planktonic phase (metagenetic Medusae). The horizontal barriers to the neritic plankton are practically those mentioned as governing the epibenthos; indeed, it would seem that the distribution of hemibenthic adults is determined by that of their more delicate larvae. Special conditions of wind and current may of course carry into the neritic zone forms which are characteristic of the open sea, and vice versa. In the neritic epibenthon of polar waters the larvae of hemibenthic forms are almost absent; indeed, the development of cold-water benthoth, whether shallow or abyssal, appears to be in most cases direct, this is, without a larval metamorphosis. The epibenthon of the open sea is described as oceanic; it consists almost entirely of holoplanktonic forms and their larvae. The chief barrier to horizontal distribution, here as elsewhere, is doubtless temperature.

For example, through the reports of the "National" cruise (German Plankton Expedition) runs the same story; one fauna characterized their course from Shetland to Greenland and Newfoundland, another the traverse of the Gulf Stream, Sargasso Sea and the Equatorial Currents. The influence of temperature may be gauged in another way: where hot and cold currents meet, occur "frontier" districts, in which the respective organisms are intermingled, and can only exist till their maxima or minima are reached. Well-marked examples of such districts occur off New Jersey (Gulf Stream and Labrador Current), in

the China Sea (warm currents of the south-west monsoon and Kamchatka Current), in the Faeroe Channel, south of the Cape (recurring of the Agulhas Current): in some of these the range of variation amounts to as much as 50° F. in the year, with the result of a colossal death-rate of the plankton, and its corollary, a rich bottom fauna, for which food is thus amply supplied. The majority of the oceanic epibenthon appears to be stenothermal; for example, few components of the well-characterized fauna of the Gulf Stream and Sargasso Sea ever reach the British shores alive, although, if current and salinity were the determining factors and not temperature, this fauna should reach to Shetland, and even to Lofoten. It will only be possible to make satisfactory distributional areas for these oceanic forms by such systematic traverses as that of the "National". At present it would seem that adjacent species have such different maxima and minima that every species must be mapped separately (compare the distribution-maps of the "National" Plankton Expedition). Some members of the epibenthon are, however, extraordinarily eurythermal and eurybathic; for example, Colactus fumarchicus ranges from 76° N. to 52° S. (excepting perhaps for 10° each side of the equator), and is apparently indifferent to depth.

In the first hundred fathoms at sea the fall of temperature is gradual and slight, and forms practically no hindrance to the **diurnal oscillation** of the oceanic epibenthon—the alleged rise and fall of almost the entire fauna. Roughly speaking, the greatest number of animals is nearest the surface at midnight; but different species sink and rise at different times, and to or from different depths. Apart from this diurnal oscillation, unfavourable conditions at the surface send or keep the fauna down in a remarkable way: for example, in the Bay of Biscay few organisms are to be found in the first fathom in bright sunlight, but on a still hot day the next few fathoms teem with life; yet after a few minutes' wind or rain these upper layers will be found almost deserted. This leads to the consideration of the **diurnal oscillation** of the plankton: apart from strong swimmers, the majority contests the tendency to sink either by some means of diminishing specific gravity (increasing floating power) or by increased frictional resistance. The former is generally attained (a) by increase of bulk through development of a fluid secretion of low specific gravity (vacuoles of Foraminiferida, Radiolaria, &c.); (b) or of a gelatinous secretion of low specific gravity (Molusseae, Chaetopoda and Echinoderm larvae, Chaetognatha, Thaliacea: the characteristic transparency of so many oceanic forms is probably attributable to this); (c) by secretion or retention of air or other gas (Physalia, Minvus, Eudone); (d) by development of oil globules (Copepoda, Cladocera, fish ova). Increased frictional resistance is obtained by flattening out the body (Pholisoma, Sabellaria) or by its expansion into lateral processes (Tommotera, Glaucus), or by the development of long delicate spines or hairs (pelagic Foraminifers, many Radiolaria, many Chaetopoda and Decapod larvae). In many cases two or more of these are combined in the same organism. Notwithstanding the above adaptations, some of which are adjustable, it is difficult to understand the mechanics of the comparatively rapid oscillations of the epibenthon, of which both causes and methods are still obscure.

It will be seen from the distribution of the Thesosomatous Pteropoda—a purely oceanic group—how difficult it will prove to draw distributional areas for classes of epibenthon. P. Pelseneer recognizes in all ten such provinces ("Challenger" Reports: "Zool." xix., xxiii.) and 42 good species: of the latter 1 is confined to the Arctic, 4 to the Antarctic province, but of the remaining 37 species and eight provinces 30% occur in all eight, 16% in seven, and only 35% have as yet been captured in a single province only.

The mesoplankton has only received serious attention during the last few years. In the "Challenger," open nets towed at various depths seemed to show the existence of a deep-water plankton, but this method gives no certain information as to the horizon of capture, the nets being open in their passage down and up. C Chun
constructed the first efficient net which could be opened and shut at known depths, using a propeller mechanism (Bibl. Zool. vol. i.); and he improved his original pattern for the "National" and "Valtivia" expeditions. The present writer has devised a net of which the opening and closing are effected from the deck by heavy weights; this has been used successfully on the "Siboga" expedition and in cruises of the "Research" (Proc. Zool. Soc., 1898). W. Garstang has constructed an ingenious net which is useful in comparatively shallow water, but is open to criticism as being too light for depths beyond 100 fathoms; and several other types are in use. The existence of a mesopelagic fauna, that is, of a plankton living between 100 fathoms from the surface and the bottom, has been generally considered as definitely proved by these nets. On the other hand, A. Agassiz, using the Tanner tow-nets, contends that while a mixture of surface and bottom species may occur in a closed sea near land, there is no intermediate fauna in the open ocean between about 200 fathoms from the surface and the bottom; his conclusions, based on negative evidence, have not met with general acceptance. Animals captured below the first hundred fathoms in the open sea (the Mediterranean, for special physical reasons, is on a special footing) are divisible into at least three categories: (1) plankton living between the surface and the bottom; e.g. Calanus finmarchicus; (2) those which, so far as we know, are purely mesopelagical and never come to the surface, for example, the Radiolarian family Tursioporidae; (3) those which, like some Schizopoda, spend a larval period in the epipelagion, and seek deeper water when adult, rising to the surface, if at all, only at night. But until the publication of the results of expeditions provided with efficient mesopelagian nets, generalizations about this fauna had better be stated with all reserve. There is, however, a certain amount of evidence to show that the mesopelagion includes different organisms in different latitudes; that surface animals of the north and south, unable to spread into the warmer surface water of lower latitudes, there sink into the cooler waters of the mesopelagion; the distributional area of such an organism will be in three dimensions bounded by isotherms (isobathytherms) and isothermabths. As with the hypobenthal, there seems to be no theoretical reason against the universal distribution of the mesopelagion.

When a more systematic investigation of the various horizons has been carried out, many of the present cases of supposed discontinuous distribution will doubtless disappear. There are, however, undisputed cases of discontinuity where physical barriers have cut across a distributional area, an example of which may be cited here. The Isthmus of Panama was apparently only upraised about Miocene times, having been previously an archipelago through which a great circumequatorial current could pass; consequently the benthos of the Panama region shows marked alliance with the Caribbean, with which it was formerly continuous, but practically none with the Indo-Pacific. To the same cause is doubtless attributable the distribution of the five Decapoda which are characteristic of the Sargasso Sea, which are circumequatorial oceanic types, only occasionally littoral: three of these are known only from the Atlantic, one occurs in the Atlantic and Pacific, one in the Atlantic, Pacific, and Indian Oceans. The damming of a great circumequatorial current by the Isthmus of Panama is probably also responsible for that dislocation of currents which resulted in the present relations of the Gulf Stream and North Atlantic Drift to the Labrador Current, and cut the Atlantic Boreal fauna into two discontinuous districts (2 and 3', fig. 3).

Under the head of discontinuous distribution, the alleged phenomenon known as bipolarity must be mentioned. In summarizing the work of the "Challenger," Sir John Murray maintained on the basis of the reports that numerous species occurred in both polar and sub-polar areas which were absent from the tropic. He regarded them as the hardy survivors of a universal fauna which had withstood that polar cooling which set in towards the close of the Mesozoic period (Murray, Trans. Roy. Soc. Edin. vol. xxxviii., 1896; G. Pfeffer, Verh. deutsch. Zool. Gesellsch. ix. 1899). This view and the facts on which it was based have been acutely contested, and the question is still far from settlement (for lists of the literature see A. E. Ostmann, Am. Nat. xxxiii. 583; and Miss E. M. Pratt, Mem. Manchester Soc. vol. xiv., 1901). As regards the purely epibenthic and sessile fauna, there are a few undoubted instances of actual specific identity; in some classes, however, such as the Echinoderms, this does not appear to hold (Hamburger Magalhaensche Sammlung; and F. Rümmer and F. Schaudinn's Fauna arctica); but even in these the general composition of the fauna and the presence of certain identical and peculiar genera seem to point to something more than a mere "convergence" due to similar environment. As regards the plankton of the two polar regions and such epibenthic forms as extend also into the tropics, the suggestion has been made that the Arctic and Antarctic benthos and plankton are really continuous by way of deep water in the main oceans, where the organisms can find a suitably low temperature. As an instance of this, C. Chun (Bezieh. zwischen dem arts. und antarkt. Plankton, 1897) cites Kratula hamata, a characteristic Arctic and sub-Arctic constituent of the epipelagion and mesopelagion, known only from the mesopelagion in the tropics, but rising to 36 fathoms at 45° S. 60° E. More exact information, such as may be expected from the various Antarctic expeditions, is needed to settle this interesting question with its far-reaching corollaries.

PLANQUETTE, ROBERT (1850- ), French musical composer, was born in Paris on the 31st of July 1850, and educated at the Conservatoire. As a boy he wrote songs and operettas for café concerts, and sprang into fame as the composer of Les Cloches de Corbeville (Paris, 1877; London, 1878). In this work he showed a fertile vein of melody, which won instant recognition. There is in his music a touch of pathos and romantic feeling, which, had he cared to cultivate it, would have placed him far above contemporary writers of opéra bouffe. Unfortunately, he did little but "croquet tickets." In the time in which originally brought him reputation, Le Chevalier Gaston was produced in 1870 with little success. In 1880 came Les Volteurs du 32ème, which had a long run in London in 1883 as The Old Guard, and La Continuera, which was translated into English as Nectarine, though never produced. In 1882 Rip van Winkle was produced in London, being subsequently given in Paris as Rip, in both cases with remarkable success. The libretto, an adaptation by H. B. Farnie of Washington Irving's famous tale, brought out what was best in Planquette's talent. In 1884 the phenomenon of an opera by a French composer being produced in London was unprecedented, and Rip van Winkle was repeated in Nell Gwynne, which was tolerably successful, but failed completely when produced in Paris as La Princesse Colombine. It was followed by La Crémalètère (Paris, 1885), Sarcouf (Paris, 1885; London, 1885, as Paul Jones, 1880), Captain Thérèse (London, 1887), La Cocarde tricolore (Paris, 1892), Le Talisman (Paris, 1892), Panurge (Paris, 1893) and Mant'ell'Qual'sous (Paris, 1897).

PLANTAGENET, a surname conveniently, but unhistorically, applied to the royal line descended from the union of Geoffrey, count of Anjou, with the empress Maud, who are now styled by historians the Angevin house. It was, historically, only a personal nickname of Geoffrey, as was "Beaucler," of his father-in-law (Henry I.) and "Curtmantel" of his son (Henry II.), and was derived from his wearing in his cap a sprig of the brome (genet) plant, "which in early summer makes the open country of Anjou and Maine a blaze of living gold." When the fashion of personal nicknames passed away, the members of the royal house were usually named from their birthplace, as Thomas" of Brotherton,"Thomas" of Woodstock," Edmund "of Woodstock," Edmund "of Langley," Lionel "of Antwerp," and so forth. But Edward I. and his younger brother, the founder of the house of Lancaster, had still nicknames respectively, as "Crochan," and "Cambrai," of the dynasty. The surname of Beaufort was adopted by the legitimate issue of John of Gaunt by Katherine Swynford, but that of Plantagenet was bestowed on Arthur, natural son
of Edward IV., who was created Viscount L'Isle. It appears, however, to have been adopted as a surname by Richard duke of York (father of Edward IV.) some twelve years before his death.

At the death of Geoffrey's grandson, Richard I., the succession was in doubt, John's elder brother Geoffrey having left, by the heiress of Brittany, a son and a daughter. But at that epoch the law of inheritance was in such a case unsettled, and their right was not clear. Arthur's fate is well known, and Eleanor, the daughter, was kept captive till her death in 1241. John's younger son Richard, king of the Romans, left a son Edmund, earl of Cornwall, with whom his line ended; his elder son Henry III. left two sons, of whom the younger was created earl of Lancaster and was grandfather of Henry, earl of Lancaster, whose heiress married John of Gaunt (i.e. Ghent). Edward I., the elder son, was grandfather of Edward III., the marriages of whose numerous children greatly affected English history. Edward his heir, the "Black Prince," left an only son, who succeeded his grandfather as Richard II., on whose death (1399) this line became extinct. Lionel, the next surviving brother of the Black Prince, left an only child Philippa, who married the earl of March, in whose heirs was the right to the succession. But John of Gaunt, the next brother, who had married the heiress of Lancaster and had been created duke of Lancaster in consequence, refounded the Lancastrian line, which obtained the throne in the person of his only son by her, Henry IV., on the deposition of Richard II., to the exclusion of the infant earl of March. His next brother, Edmund of Langley, who was created duke of York (1385), founded the Yorkist line, and was father, by a daughter and co-heiress of Pedro the Cruel, king of Castile, of two sons, Edward, second duke, who was slain at Agincourt, and Richard, earl of Cambridge, who by marrying the granddaughter and eventual heiress of Lionel's daughter Philippa, brought the right to the succession into the house of York.

Between their son and Henry VI. (grandson of Henry IV.) and Edward and Henry, sons and heirs of these rivals, was fought out the dynastic struggle known as "the Wars of the Roses," which proved fatal to several members of both houses. Richard, the son of Richard and Anne Mortimer, became third duke of York (1425), and was made protector of the realm 1454-1455, being finally declared heir to the throne on the triumph of his side in 1460; but he was slain at the battle of Wakefield (Dec. 31, 1460). Of his four sons, Edward, the eldest, became king as Edward IV. within three months of his death; Edmund, the second, was slain with his father at Wakefield; George, the third, duke of Clarence, was put to death in 1478; and Richard, the fourth, duke of Gloucester, became king as Richard III. in 1483 and was slain on Bosworth Field in 1485. Of his two surviving sons, Edward and Richard (the princes in the Tower), had been mysteriously put to death in 1483, so that the only male descendant of the house of York, and indeed of the whole Plantagenet race, was the duke of Clarence's son Edward, earl of Warwick (grandson of "the Kingmaker"), who was imprisoned by Richard III.'s (his father's younger brother) in 1483, and finally executed on Tower Hill, under Henry VII., in 1499.

Of the house of Lancaster, the only son of Henry VI. was slain after the battle of Tewkesbury (1471), while Edmund (Beaufort) duke of Somerset, a grandson of John of Gaunt, was slain at the first battle of St Albans (1459), and all his three sons were slain or beheaded. On the death of Henry VI. and his son in 1471, so complete was the extinction of his line that its representation vested in the heirs of the two daughters of John of Gaunt by the heiress of Lancaster, viz. Philippa queen of Portugal and Elizabeth countess of Huntingdon. But by his second wife, the heiress of Castile, John had left an only daughter, Mary of Castile and Leon, who also left descendants, and from his third but ambiguous union sprang the house of Beaufort, whose doubtful claims to his heirship passed with his great-granddaughter Margaret, by her husband Edmund Tudor, to their son Henry VII. Although Henry was careful to claim the crown in his own right (1483), he soon fortified that claim by marrying Elizabeth, eldest daughter of Edward IV., and rightful heiress to the throne. The marriage of their eldest daughter Margaret to James IV. of Scotland in 1503 resulted in the accession of James VI. of Scotland, a century later, as next heir to the throne (see Stewart).

Although no other dynasty has reigned so long over England since the Norman Conquest, the whole legitimate male issue of Count Geoffrey Plantagenet is clearly proved to have become extinct in 1499. Of its illegitimate descendants the house of Cornwall was founded by Richard, a natural son of Richard, king of the Romans and earl of Cornwall, who was ancestor of the line of Cornwall (House of the Bowl, temp. Henry VI., of the Cornwalls, "house of Burford," and other families; but the principal house is that which was founded, at a later date, by Sir Charles Somerset, natural son of Henry (Beaufort) duke of Somerset (beheaded 1464), who was created earl of Worcester in 1513, and whose descendant Henry, marquess and earl of Worcester, obtained the dukedom of Beaufort in 1683. From him descend the ducal house, who bear the ancient arms of France and England, quarterly, within a bordure. (J. H. R.)

PLANTAIN (Lat. plantago), a name given to certain plants with broad leaves. This is the case with certain species of Plantago, Alisma and Musa, to all of which the term is popularly applied. The species of Plantago are mostly weeds with a dense number of radical leaves and scapes bearing terminal spikes of small flowers; the long spikes of P. major, when in seed, are used for feeding cago-birds; P. lanceolata, so called from its narrow lanceolate 3-6-ribbed leaves, is popularly known as ribwort; Alisma P. is the water-plantain, so called from the resemblance of its broad ribbed aerial leaves to those of P. major. The tropical fruit known as plantain belongs to the genus Musa (see Banana).

PLANTATION (Lat. plantare, to plant), literally the placing of plants in the ground, hence a place planted or a collection of growing things, &c., particularly used of ground planted with young fruit trees. This term was early applied, in a figurative sense, to the settlement of people, and particularly to the colonization of North America in the early part of the 17th century and to the settlement of Scotch and English in the forfeited lands in Ireland (see below). The practice of sending convicted criminals to serve on the plantations in the colonies became common in the 17th century (see DEPORTATION). These plantations were chiefly in the cotton, sugar and tobacco growing colonies, and the term "plantation" is thus particularly applied to estates in tropical or semi-tropical countries; the proprietors of such estates are specifically styled "planters."

The negroes on the plantations of the Southern States of North America sang their songs and hymns and danced to tunes which were traditional, and are frequently known as "Plantation Songs." It has been claimed for some of them that they represent the folk songs brought by the first slaves from Africa; but the more generally accepted view is that they were those European hymn and song tunes which the negroes picked up from the revivalist preachers or from the Europeans around them, and adapted to their own strongly marked rhythms, which are certainly of African origin. The earliest song which became familiar to those outside the Southern States was "Jim Crow," sung by Dan Rice, and introduced to England about 1836. The "Jubilee Singers, a troupe from Fisk University, Nashville, Tennessee, toured the United States and Europe in 1871; but the great popularity of the negro songs and dances, and the traditional instruments, the bones and tambourine (the banjo was not originally used by the genuine negro), was due to the so-called " negro minstrel" troupes, of which the best known in England were Christy's, whence the generic name of Christy Minstrels, and later of the Moore and Burgess troupe at St James's Hall, London, started in 1862 and finally dissolved in 1904.

The best collection of genuine "plantation songs" and their words is Slave Songs of the United States (New York, 1871); see also
PLANTIN

C. L. Edwards, Bahama Songs and Stories (Boston, 1898); J. B. T. Marsh, The Story of the Jubilee Singers (Boston, 1899); and articles by G. W. Cable on "The Creole Slave Dance" and "Creole Slave Songs," in the Century, February and April 1886.

Plantation of Ulster.—The Irish rebellion, which had disturbed Ulster during the closing years of Elizabeth's reign, was followed under James I. by further trouble, due partly to the inability of the English government to understand the system of land ownership prevalent in Ireland. At this time the chief offenders against the authority of England were the earls of Tyrconnell and Tyrone, but in September 1607 these once powerful nobles fled from the country. The English lawyers declared that the extensive estates which they held, not in their personal capacity, but as the heads respectively of the tribes of O'Neill and O'Donnell, had become the property of the English crown; and the problem which now confronted them was what to do with the same condition of Ulster. But Chichester was much too large to be cultivated properly by the scanty population living thereon. The idea of a plantation or colonization of Ulster, which was put forward as an answer to this question, is due mainly to Sir Arthur Chichester, the Irish lord deputy; its object was to secure the better cultivation of the land and to strengthen the English influence in Ulster by granting estates to English and Scottish settlers. Chichester proposed that the native inhabitants should be allowed to occupy as much land as they could cultivate, for he said, "that many of the natives in each county claim freehold in the lands they possess, and albeit these demands are not unreasonable, they must be had and is almost impossible to displacethem." Even if this advice were carried out on a generous scale, the deputy considered that there would be abundance of land to offer to colonists, and also to reward the class of men known as servitors, those who had served the English king in Ireland. He submitted his ideas to Sir James Ley and Sir John Davies, two of the ministers of James I.; they reported to the English privy council, which signified its approval, and after the question had been illuminated by Bacon's great intellect, a committee was appointed to make the necessary arrangements. But those responsible for the plantation made one cardinal mistake, a mistake which was to cost the country much in the future. They rejected Chichester's idea of allotting land to the natives on a liberal scale, preferring to turn them out and to parcel out the whole of the forfeited district anew.

The forfeited lands lay in six counties, Tyrone, Donegal, Armagh, Fermanagh, Cavan and Coleraine (Londonderry), and the scheme for the plantation having been drawn up, the necessary survey began in May 1609. This was very inaccurate; but it served its purpose. The land was divided into three sections. One block of land was set apart for English and Scottish settlers, who were not to be allowed to have any Irish tenants; another was allotted to the servitors, who might have land, either English or Irish tenants; and a third was reserved for the Irish. Applications were then entertained from those willing to take up the land, and under Chichester's direction the settlement was proceeded with. The land was divided into portions of 1000, 1500 and 2000 acres, each colonist undertaking in return for his grant to build a castle or a walled enclosure, and to keep, train and arm sufficient men for its defence. Moreover he must take the oath of supremacy to James, and must not alienate his estate to an Irishman. He was given two years in which to do the necessary building; during this period he was freed from paying rent, but afterwards he must pay a quit-rent to the Crown. A scale of rents was drawn up, the native Irish paying at rates higher than the English and Scottish settlers. Out of the forfeited lands provision was made for the maintenance of churches and schools, which were to be erected in conformity with the scheme.

The work progressed very slowly and much of the building was not even begun within the required time. Then in 1611 James I., who had from the first taken a lively interest in the plantation, sent Lord Carew to report on it. Carew's inspection did not reveal a very favourable condition of affairs, and in 1615 Sir Josiah Bodley was sent to make a further report about the progress of the work. A third report and survey was made three years later by Nicholas Pynnar, who found in the six counties 1974 British families, with 6215 men capable of bearing arms. He said that even on the lands occupied by the colonists the cultivation of the soil was still very much neglected. The words spoken by Bacon in 1617 with reference to the plantation had come true. "Take it from me," he said, "that the bane of a plantation is when the undertakers or planters make such haste to a little mechanical present profit, as disturbeth the whole frame and nobleness of the work for times to come." Another survey took place in 1622, when various changes were suggested, but no serious alterations were made. On the whole the plantation had been a failure. Very few of the settlers had carried out their undertaking. In many cases the Irish had remained on the land allotted to the colonists, living under exacted a rent and as the land at Chichester, and plantation, and holding on "whether the legal landlords liked it or not." As actually carried out the plantation dealt with 511,465 acres. Two-fifths of this was assigned to British colonists, being divided about equally between Englishmen and Scotchmen. Rather more than one-fifth went to the Church and about the same amount to the servitors and the natives. The best settlers were the Scots, although their tendency to marry with the Irish was noted and condemned during the early years of the settlement.

An important part of the plantation was the settlement of Chichester and Coleraine by the corporation of the city of London. Receiving a grant of practically the whole of the county the corporation undertook to spend £20,000, and within two years to build 200 houses in Derry and 100 in Coleraine. This was the most successful part of the settlement, and to it Londonderry owes its present name.

The expulsion of the Irish from the land in which by law and custom they had a certain proprietary and hereditary right, although not carried out on the scale originally contemplated, naturally aroused great indignation among them. Attacks on the settlers were followed by reprisals, and the plantation may fairly be regarded as one of the causes which led to the terrible massacre in Ulster in 1641. During Elizabeth's reign a scheme for the plantation of Munster was considered, and under Charles I. there was a suggestion for the plantation of Connaught, but eventually both were abandoned.

The "Orders and Conditions of Plantation" are printed in Walter Harris's Hibernia (Dublin, 1770); and in George Hill's Historical Account of the Plantation in Ulster, 1608-1620 (Belfast, 1877). See also R. Gardner, History of England (1899), vol. i.; and R. Bagwell, Ireland under the Stuarts (1909), vol. i.

PLANTIN, CHRISTOPHE (1574-1589), French printer, was born in a village near Tournai (probably Saint-Avustin). He was born on January 1, 1574, and married in that town, settled in 1549 as bookbinder in Antwerp, where he was soon known as the first in his profession. A bad wound in the arm seems to have been the cause that first led him (about 1555) to apply himself to typography. The first known book printed in his office was La Institutione di una fanciulla nata nobilmente, by J. M. Bruto, with a French translation, and this was soon followed by many other works in French and Latin, which in point of execution rivalled the best printing of his time, while the masters in the art of engraving then flourishing in the Netherlands illustrated many of his editions. In 1562, Plantin himself being absent in Paris, his workmen printed an heretical pamphlet, which caused his moveables to be seized and sold. It seems, however, that he recovered a great deal of the money, and in 1563 he associated himself with some friends to carry on his business on a larger scale. Among them were two grand-nephews of Dan. Bomberg, who furnished him with the fine Hebrew types of that renowned Venetian printer. His editions of the Bible in Hebrew, Latin and Dutch, his Corpus juris, Latin and Greek classics, and many other works produced at this period are renowned for their beautiful execution and accuracy. A much greater enterprise
was planned by him in those years—the publication of a *Biblia polyglotta*, which should fix the original text of Old and New Testaments on a scientific basis. In spite of clerical opposition he was supported by Philip II, King of Spain, who sent him the learned Benedictus Arias Montanus to take the leading part in the work of editorship. With his zealous help the work was finished in five years (1560-1573, 8 vols. folio). Plantin earned little profit, but received the privilege of printing all liturgical books for the states of King Philip, and the office of “prototypographer regius.” Though outwardly a faithful son of the church, he was till his death the partisan of a mystical sect of heretics; and it is now proved that many of their books published without the name of a printer came from his presses together with the missals, breviaries, &c., for the Roman Catholic Church.

Besides the polyglot Bible, Plantin published in those years many other works of note, such as editions of St Augustine and St Jerome, the botanical works of Dodoneus, Clusius and Lobelius, the description of the Netherlands by Guicciardini, &c. In 1575 his printing-office reckoned more than twenty presses and seventy-three workmen, besides a similar number that worked for the office at home. But in November 1576 the town was plundered and in part burnt by the Spaniards, and Plantin had to pay an exorbitant ransom. He established a branch of his office in Paris; and when in 1585 the states of Holland sought a typographer for the newly erected university at Leiden, he left his much reduced business in Antwerp to his sons-in-law John Morentorf (Moretus) and Francis van Ravelinghen (Raphelengius), and settled there. When in 1585 Antwerp was taken by the prince of Parma and affairs became there more settled, he left the office in Leiden to Raphelengius and returned to Antwerp, where he laboured till his death on the 1st of July 1589. His son-in-law, John Moretus, and his descendants continued to print many works of note “in officina Plantiniana,” but from the second half of the 17th century the house began to decline. It continued, however, in the possession of the Moretus family, which religiously left everything in the office untouched, and when in 1876 the town of Antwerp acquired the old buildings with all their contents, for 1,200,000 francs, the authorities were able with little trouble to create one of the most remarkable museums in existence (the Musée Plantin, opened August 19, 1877).

**PLANTS.**

In the most generally used sense, a plant is a member of the lower or vegetable order of living organized things; the term is also popularly applied to the smaller herbaceous plants, thus excluding trees and shrubs. The early use of the word is for a twig, shoot, cutting or sapling, which was the meaning of Lat. *planta* (for *planta*, the root being that seen in *pluvis*, flat, cf. Gr. *παρυς*, broad; *planta* thus meant a spreading shoot or sucker). Other meanings of "plant" are derived from the verb "to plant," (Lat. *plantare*, to fix in position or place). It is thus used of the flat-topped, many-stemmed growing things necessary for the carrying on of an industry or business, and in colloquial or slang sense, of a swindle, a carefully arranged plot or trap laid or fixed to deceive; cf. also *Plantation*. In the following sections the botanical sense of the word is followed, the term being used generally as opposed to "animals."

**Classification of Plants.**

Some account of the history of plant classification and the development of a natural system in which an attempt is made to show the actual relationships of plants, is given in the article *Botany*. The plant world falls into two great divisions, the higher or flowering plants (*Phanerogams*), characterized by the formation of a seed, and the lower or flowerless plants (*Cryptogams*), in which no seed is formed but the plants are disseminated by means of unicellular bodies termed spores. The term *Cryptogam* is archaic, implying a hidden method of reproduction as compared with the obvious method represented by the flower of the *Phanerogam*; with the aid of a good microscope it is, however, easier to follow the process of fertilization in many Cryptogams than in the flowering plants. These two main divisions are moreover of unequal value, for the Cryptogams comprise several groups differing from each other by characters as marked as those which separate some of them from the *Phanerogams*. The following groups or sub-kingdoms are those which are now generally recognized:

1. *Thallophyta.*
2. *Bryophyta.*
3. *Pteridophyta.*
4. *Spermatophyta.*

*Thallophyta* are the most lowly organized plants and include a great variety of forms, the vegetative portion of which consists of a single cell or a number of cells forming a more or less branched thallus. They are characterized by the absence of that differentiation of the body into root, shoot, and leaf which is develope in the higher plants, and by the simplicity of their internal structure. Both sexual and asexual reproduction occur, but there is usually no definite successions of stages. In general it is only that alternation of sexual generation (gametophyte and sexual heterogametophyte) which characterizes the higher groups. The group has until recent years been regarded as comprising three classes distinguished by well-marked botanical and physiological differences (including the *Seaweeds*) which contain chlorophyll, the Fungi which have no chlorophyll and therefore lack a saprophytic or parasitic mode of life, and the Lichens which are compound organisms consisting of a fungus and a alga or cyanophyte (or both). The uncritical student of the older books is recommended to recognize *Thallophyta* and *Lichens*. The study of phylogeny has suggested four fundamental phyla in the following sequence: (1) Bacteria; (2) Cyanophyceae (blue-green algae); (3) Flagellatae; (4) Myxomycetes (Siame-fungi); (5) Peridinea; (6) Conjugatae; (7) Chlorophyceae (Green Algae); (8) Heterocon- tae; (9) Chlorophyceae (Green Algae); (10) Characinae (Sponges); (11) Rhodophyceae (Red Algae); (12) Eumycetozoa (Fungi); (13) Phycyoomycetozoa (Algal fungi); (14) Phaeophyceae (Brown Algae). Bacteria (see *Bacteriology*) and Cyanophyceae (see *Algae*), which are often grouped together as Schizophyta, are from points of view both structure and reproduction extremely simple organisms, and stand apart from the remaining groups, the last being generally regarded as the most derived in structure, at any rate, from the *Flagellatae*, a group of unicellular aquatic organisms combining animal and plant characteristics which may be regarded as the starting-point of unicellular Thallophytans on the one hand and of the *Protozoa* on the other.

Thus simple and compound *Heteroconetae*, Chlorophyceae and Phaeophyceae show an obvious connexion with the *Flagellatae*; the *Peridinea* may be regarded as the result of the development of the spore in the *Characinae*, Diatomaceae cannot be directly connected; the origin of the *Rhodophyceae* is also obscure; while the *Characinae* are an advanced and isolated group (see *Algae*). The *Myxomycetozoa* (g.s.) or Myxomycetozoa are a group without chlorophyll, of simple structure and isolated position. The algal fungi (*Phycyoomycetozoa*) are obviously derived from the *Green Algae*, while the remaining Fungi, the *Eumycetozoa*, appear to have sprung from the same stock as the *Rhodophyceae* (see *Fungi*). Owing to the similarity of structure and mode of life it is convenient to treat the Lichens (g.s.) as a distinct class, while recognizing that the component fungus and alga are representatives of their own classes.

The *Bryophyta* and *Phaeophyta* have sprung from the higher *Thallophyta*, and together form the larger group *Archegoniatae*, so-called from the form of the organ (*archegonion*) in which the eggs or sperm are developed. The *Archegoniatae* are characterized by a well-marked alternation of gametophytes and spore-bearing generations; the former bears the sexual organs which are of characteristic structure and known as antheridia (male) and archegonia (female) respectively; the fertilized egg or spore, on germination gives rise to the spore-bearing generation, and on the spore germination give rise directly or indirectly to a second gametophyte.

The *Mosses* and Liverworts (see *Bryophyta*) include forms with a more or less leaf-like thallus, such as the liverworts, and forms in which the plant shows a differentiation into a stem bearing remarkably simple leaves, as in the true mosses. They have no true roots, and their structure is purely cellular or conducting bundles of a very simple structure are present. The independent plant which is generally attached to the soil by hair-like structures is the sexual generation, the sporophyte is a stalked or sessile capsule.
which remains always attached to the gametophyte from which it derives the whole or part of its nourishment.

The embryonic shoot of the plant (see Pteridophyta) have on the other hand a well developed independent sporophyte which is differentiated into stem, leaf and root with highly organized internal structure, excluding true vascular bundles. In general structure they approach more or less the vascular system which forms the Collectively the Vascular Plants as contrasted with the Cellular Plants—Thallophyta and Bryophyta. The gametophyte is a saprophytic plant which shows varying degrees of independence affording an interesting transition to the higher group.

Spermatophyta are characterized by an extreme reduction of the gametophyte generation. The sporophyte is the plant which is developed in the cell wall; the leaf and root show a wonderful variety of form; the internal structure also shows increased complexity and variety as compared with the other group of vascular plants, the Pteridophyta. The spores, as in the heterosporous Ferns, are either pollen—sacs borne in macrosporangia (sacs) or spores (sperm) known as carps. The fertile leaves or sporophylls are generally aggregated on special shoots to form flowers which may contain one or both kinds. The microspores are set free from the sporangium and carried generally by wind or insect agency to the vicinity of the macrospore, which never leaves the ovule. The male gametophyte is made up by one or few cells and, except in a few primitive forms where the male cell still retains the motile character as in the Pteridophyta, is carried passively to the macrospore in a liquid, the pollen grain, the pollen tube. The Spermatophyta are thus land plants par excellence and have, with the few exceptions cited, lost all trace of an aquatic ancestry. Aquatic plants occur among them but these are relicts of land plants in an aquatic environment. After fertilization the female cell, now called the oospore, divides and part of it develops into the embryo (new sporophyte), which remains dormant for a time still protected by the carpel, which later develops into the seed. The seed is a new structure characteristic of this group, which is therefore often referred to as the Seed-plants. The seed is set free from the parent plant and serves as the means of dissemination (see FLOWER; POLLINATION; Fruit, and Seed). The Spermatophyta fall into two classes, Gymnosperms (q.v.) and Angiosperms (q.v.); the former are the more primitive group, appearing earlier in geological time and showing less differentiation of form than the true flowering plants to the Pteridophyta. A recently discovered fossil group, the Pteridospermae (see Palaeobotany) have characters intermediate between the Pteridophyta and the more primitive seed-plants.

In Gymnosperms—so-called because the ovules (and seeds) are borne on an open sporophyll or carpel—the microsporophylls and macrosporophylls are not as a rule associated in the same shoot and are generally arranged in cone-like structures; one or two small prothallial cells are formed in the germination of the microspore; the male cells are in some older members of the group motile though usually passive. The ovule is not enclosed in an ovary, as in the other groups, but is a stalked cone composed of the central thallus, in the upper part of which are formed several rudimentary archegonia. The fertilized egg-cell (oospore) forms a filamentous structure, the prothallus, from which the young sporophyte or embryo develops, one only as a rule reaching maturity. The embryo consists of an axis bearing two or more cotyledons and ending below in a radicle; it lies in a generally copious food-storing tissue (endosperm) which is the remains of the female prothallus.

The plant has a well-developed main root (tap-root) and a single or branched leaf stem which is provided with a means of secondary increase in thickness. The leaves are generally tough-skinned and last for more than one season. The Angiosperms, which are much the larger class, derive their name from the fact that the carpel or carpels form a closed chamber, the ovary, in which the ovules are developed—associated with this is the reduction of the sporophytic state to a condition of extreme size. The pollen grain is deposited. The sporophylls and carpels are generally associated with other leaves, known as the perianth, to form a flower; these subsidiary leaves are protective and attractive in function and their development is correlated with the transport of pollen by insect agency (see Angiosperms; Pollination, and Flower). The male gametophyte is sometimes represented by a transitory prothallial cone, which, as in the male cells, develops into a large "suspensory" cell and a terminal embryo. Endosperm is formed as the result of the fusion of the second male cell with the so-called "definitive nucleus" of the embryo-sac (see Angiosperms) and consists of the male cells carried in the cotyledons) or two (Dicotyledons) cotyledons, which protect the stem bud (pseudocotyledon) of the future plant, and ending below in a radicle. The seed is enclosed when ripe in the fruit, a development of the ovary as a result of fertilization of the egg-cell. (A. B. H.)
cavity as "the cell," and the contained protoplasm or other substances, if present, as cell-contents. This is in accordance with the original use of the term "cell," which was applied in the 17th century to the cavities of plant-tissues on the analogy of the cells of honeycomb. The use of the term to mean the individualized nucleated mass of living protoplasm, whether with or without a limiting membrane, primitively forms the proximate histological element of the body of every organism, dates from the second quarter of the 19th century. For a more detailed description of the cell see Cytology and the section on Cytology of Plants below). In all but the very simplest forms the plant-body is built up of a number of these cells, associated in more or less definite ways. In the higher (more complicated) plants the cells differ very much among themselves, and the body is composed of definite systems of these units, each system with its own characteristic structure, depending partly on the characters of the component cells and partly of the higher plants. The term parenchyma is applied to tissues whose cells are isodiametric or cylindrical in shape, parenchyma tissues consisting of long narrow cells, with pointed ends.

We may now proceed to a systematic account of the anatomy of the different groups of plants, beginning with the simplest, and passing to the more complicated forms.

Thallophyta.—The simplest members of both the Algae and the Fungi (p. z.) (the two divisions of the Thallophyta, which is the lowest of the four great groups into which the plant-kingdom may be divided) are the plants known as single-celled algae. In the Algae such a cell consists essentially of: (1) a primary system of protoplasm provided with (2) a nucleus and (3) an assimilating apparatus consisting of a coloured protoplasmic body, called a chloroplast, the pigment of which in the pure green forms is chlorophyll, and which may then be called a chloroplast. The whole of these living structures are covered externally by the dead cell-membrane (fig. 1 A). It is from such a living and assimilating cell, performing as it does all the vital functions of a green plant, that, according to current theory, all the different cell-forms of a higher plant have been differentiated in the course of descent.

Among the Green Algae the differentiation of cells is comparatively slight. Many forms, even when multicellular, have all their cells identical in structure and function, and are often spoken of as "physiologically unicellular." These are commonly joined end to end in simple or branched filaments. Such differentiation as exists in the higher types mainly takes two directions. In the first forms the cell or cells which attach the plant to the substratum have a peculiar form, containing chlorophyll and constituting a rudimentary fixing organ or rhizoid (fig. 1 C). In certain types living on damp soil, the rhizoids penetrate the substratum, and in addition to fixing the plant absorb substances (dissolved salts) from the substratum (fig. 1 B and D).

The second type of differentiation is that between supporting axes and assimilating appendages. The cells of the axis are commonly baseless and so have the form of chlorophyll bearing appendages (Drapparnalia). This differentiation is parallel with that between stem and leaf of the higher plants. In the group of the Siphonaceae both these types of differentiation may exist in the single, long, branched, tube-like and multicellular "cell" (coenecium) which here forms the plant-body. Prototaxis (fig. 1 B) is an example parallel with Oedogodium; Bryopsis, with Drapparnalia. In Conotus the imitation of a higher plant by the differentiation of fixing, supporting and assimilating organs (root, stem and leaf) from different branches of the single cell is strikingly complete. In the Siphonaceous family of Codiaeaceae the branches of the primitive cell are considerably interwoven, and there is evidence that a dense tissue-like structure is often produced. In this we get a further differentiation between the central tubes (branches of the primitive cell), which run in a longitudinal direction through the body of the plant, and the small irregular strands or filaments which supply the cells with food substances from one region to another, and the peripheral ones, which are directed perpendicularly to the surface of the body, ending blindly there, contain abundant chlorophyll, and are the assimilating organs (fig. 1 E).

None of the existing Red Seaweeds (Rhodophyceae) has a unicellular body. The thallus in all cases consists of a branched filament of cells placed end to end, as in many of the Green Algae. Each branch grows simply by the transverse division of its apical cell. The branches may be quite free or they may be united laterally to form a solid body of more or less firm and compact consistency. This may have a radial stem-like organization, a central cell-though growing from everywhere on every cell a number of small cells (siphonaceous) which together form a cortex round the central thread, the whole structure having a cylindrical form which only branches when the short transverse branches from the central thread grow out beyond the general surface and forms in its turn a new central thread, from whose cells arise new short branches. Or the thallus may have a leaf-like form, the branches from the central threads forming the midrib growing out mainly in one plane, together forming a lamina, extended right and left of the midrib. Various variations and modifications of these forms exist. In all cases, while the internal threads which bear the cortical branches consist of homogeneous cells, the outer cells have a differentiated structure, mainly for conduction of food substances, the superficial cells of the branches themselves are packed with chromatophores and form the chief assimilating tissue of the plant. In the bulky forms the divisions of branches, in addition to the chromosome cells, and, pushing among the already-formed threads in a longitudinal direction, serve to strengthen the thallus by weaving its original threads together. The cells belonging to any given thread may be recognized at an early stage of growth, because each cell

---

**Fig. 14.—Examples of the differentiation of the tissue of plants.**

J. End of hydroid of the Moss *Minium*, showing particularly thin oblique end-wall. No pits.
K. Optical section of two adjacent lepto-pods of the Moss *Polytrichum juniperium*. The lepto-pods are living and nucleated. They bulge in the neighbourhood of the very thin cross-wall. Note resemblance to 2 X and 2 Y.
L. Optical section of cell of parenchyma in the same moss. Embedded in the protoplasm are a number of starch grains.
M. Part of elongated stereid of a Moss. Note thick walls and oblique slit-like pits with opposite inclination on the two sides of the cell seen in surface view.
N. One side of the end of hydroid (tracheid) of a Pteridophyte (fern), with scalariform pits.
O. Optical section of two adjacent lepto-pods (sieve-tube segments) of *Pteridophyre*, with sieve plates (s. pl.) on oblique end-wall and side-walls.
P. Part of spiral hydroid (tracheid) of Phanerogam (Flowering Plant).
Q. Three segments of a "pitted" vessel of Phanerogam.
R. Optical section of lepto-pod (sieve-tube segment) of Phanerogam, with two protodi (companion) cells, s. pl., sive-plate.
S. Optical section of part of thick-walled stereid of Phanerogam, with almost obliterated cavity and narrow slit-like oblique pits.
T. Part of vertical section through blade of typical leaf of Phanerogam. u.e., Upper epidermal cells, with (c) cuticle. (p) Assimilating (palisade) cells, s.p., Assimilating (spongy) cells with large lacunae. i.e., Lower epidermis, with st., stoma.
U. Absorbing cell, with process (root-hair) from plications layer of root of Phanerogam.
V. Endodermal cell of Phanerogam, with suberized central band on radial and transverse walls.

on the method of association. Such a system is called a tissue-system, the word tissue being employed for any collection of cells with common structural, developmental, or functional characters to which it may be conveniently applied. The word is derived from the general resemblance of the texture of plant substance to that of a textile fabric, and dates from a period when the fundamental constitution of plant substance from individual cells was not yet discovered. It is convenient here to define the two chief types of cell-form which characterize tissues of the higher plants. The term parenchyma is applied to tissues whose cells are isodiametric or cylindrical in shape, parenchyma tissues consisting of long narrow cells, with pointed ends.
is connected with its neighbours belonging to the same thread by two depressions or pits, one at each end. The common wall separating the pits of the two adjoining cells is pierced by strands of cytoplasm (fig. 2). The thallus structure, consisting of the two pits and the wall between is known as a thallus pit. There are two kinds of cells not belonging to the same branch, are, however, formed at a later stage.

Other lower forms of Brown Seaweeds (Phaeophyceae) have a thallus consisting of simple or branched cell threads, as in the green and red forms. The lateral union of the branches to form a solid thallus is not, however, so common, nor is it carried to so high a degree as in the brown higher Fungi, particularly the elaterulatales (stipe), which is formed, by cell division in all directions of space. In the Laminariaceae this tissue is formed by cell division at what is called a very growing point, i.e., a meristematal collenchyma, the region occupying the whole of a certain transverse zone of the thallus, and cutting off new cells to add to the permanent tissue on both sides. In the Fucales, on the other hand, there is a single prismatic apical cell situated at the bottom of the growing margin of the thallus, which cuts off cells from its sides to add to the peripheral, and from its base to add to the central permanent cells. The whole of the tissue of the plant is formed by the division of these apical cells, whereas the thallus wall of the brown higher Fungi, however, the main features of their differentiation are the same.

In the Laminariaceae, is well seen, that which is derived from the primitive apical cell, has, as far as can be seen, the same features as the higher Fungi, consisting of cells, formed by cell division in all directions of space. In the Laminariaceae there is a differentiation of the outer, and another of the internal tissues. The outer, or epidermal, cells which are specialized for the assimilation of the thallus, form a colourless, or nearly colourless, parenchymatous cortex, which acts as a storage food tissue (fig. 1, G), and surrounds a central medulla of elongated conducting cells. The latter are often swollen at the ends, so that the thallus itself is a continuous, transverse tube, larger in diameter than if the cells were of uniform width along their entire length.

Cells of this type are often called "trumpet-hyphae" (though they have no connexion with the hypheal of Fungi), and in some cases they take the place of the rhizoid-like branch, which is derivatives of the thallus wall of higher plants. It is well shown by the "pipe-tub" of the larger plants, which are always developed in plants where the region of assimilative activity is local in the plant-body, as it is in practically all the higher plants. This is the case in the Fucaceae, and in a very marked degree in the Laminariaceae in question, where the assimilative front is borne at the end of an extremely long supporting and conducting stipe. A similar state of things exists in some of the higher plants, where the Red Red seaweeds, e.g., the Fucus, or to meet the demands for conduction in such cases always shows some of the characters described. It is known as leptorhiza, each cell being a leptorhiza (fig. 1, H). In addition to the cell types described, certain other types are there, these but little differentiated, bearing in some cases a relationship to the rhizoid-like branches of the cells to grow out, mostly from the cells at the periphery of the medulla, and grow down between the cells, strengthening the whole tissue, and let in the Red Seaweeds, the Thallus thickening in a more or less remarkable thickening of the thallus. In many Laminariaceae the thallus also grows regularly in thickness by division of its surface layer, adding to the subjacent permanent tissue and thus forming a secondary meristem.
A sufficient description of the thallus of the liverworts will be found in the article Bryophyta. We may note the universal occurrence on the lower surface of the thallus of fixing and absorbing rhizoids in accordance with the terrestrial habit of the Great Liverwort family. The Marchantiaceae (see article Bryophyta) show considerable tissue-differentiation, possessing a distinct assimilative system of cells whose course is associated with the superficial leaves and arising from the basal cells of large cavities in the upper part of the thallus. These cavities are completely roofed by a layer of cells; in the centre of the roof is a pore surrounded by a ring of special cells, in which are usually arranged a number of strong hydroids, attached by thick-walled rhizoids to the lacunae, mesophyll and stomata, which form the assimilative and transpiring (water-evaporating) apparatus in the leaves of flowering plants. The frondose (thalloid) Jungermanniaceae show no other solved problem of assimilation than the presence of an assimilating layer, so that the cells of the thallus usually have more chlorophyll than the rest. In three genera—Blyttia, Symphyogyna and Hymenophyllum—there are one or more strands or bundles consisting of long-walled fibrous-like (prosenchymatous) cells, by which conduct water through the thallus, the assimilating parts of which are in these forms often raised above the soil and are comparatively remote from the rhizoid-bearing (water-absorbing) region. Such differentiations are found in those cases where the conducting cells are more or less strongly pressed against their neighbors, so that they form hydrom. The sporogonium of the liverworts is in the simpler forms simply a spore-capsule with arrangements for the development, protection and distribution of the spores. As such it is a modified and greatly simplified, but still a small and peculiar group of these plants, the Anthoceraceae, a distinct assimilating and transpiring system is found in the wall of the very long cylindrical capsule, clearly rendering the sporogonium largely independent of the supply of elaborated organic food from the thallus of the mother plant (the gametophyte). A richly chlorophyllous tissue with numerous intercellular spaces containing protoplasm and protoplasmic strands is found in those of the vascular plants (see below). If the axis of such a sporogonium were prolonged downwards into the soil to form a fixing and absorptive root, the whole structure would become a phytophore. But the greater number of Liverworts, in plant structure, means no more all respects the leading features of the sporogyne or ordinary vegetative and spore-bearing individual in Pteridophytes and Phanerogams. These facts, among others, have led to the theory, plausible in some respects, of the origin of this sporogyne by descent from an Anthocerace-like sporogonium (see Pteridophyta). But in the Bryophytes the sporogonium never becomes a sporogyne proper, but consists of branched cell-threads (rhizoids) which send up from the soil, fixing the plant and absorbing water from it. For the histology of the comparatively simple but in many respects aberrant Bog-mosses (Sphagnaceae), see Bryophyta.] The stems of the liverworts are one of the most characteristic features. In a few cases there is a special surface or epidermal layer, but usually all the outer layers of the stem are composed of brown, thick-walled, lignified, prosenchymatous, fibre-like cells forming the perisporon. The outermost layer of cells which forms the outer cortex. This passes gradually into the thinner-walled parenchyma of the inner cortex. The whole of the cortex, stem and parenchyma alike, is commonly living, and its cells are often filled with air. The stem is usually unbranched, or a name pitted (fig. 1, 1). The hydrom strand has in most cases no connection with the veins, but runs up the stem and spreads out below the sexual organs or the foot of the sporogonium. It has been shown that it conducts water with a high velocity. In the case of the liverworts there is a similar strand, which is of course not in direct connection with the cortex, but continues the conduction of water from the strand of the gametophyte axis. In the aquatic, semi-aquatic, and xerophilous types, where the whole surface of the plant absorbs water, perpendicularly in the first two cases and during rain in the last, the hydron strand is either much reduced or altogether absent. In accordance with the general plan of structure the assimilation is localized (i.e., where the plant lives on soil from which it absorbs its main supply of water) by means of its basal rhizoids that a water-conducting (hydron) strand is developed. The leaves of the liverworts are generally small, bearing few if any stellate hairs, being single in square or oblong assimilating (chlorophyllous) cells. In many cases the cells bordering the leaf are produced into teeth, and very frequently they are thick-walled so as to form a supporting rim. In this manner the cells of the leaf have become studded with several layers of cells. These are elongated in the direction of the length of the leaf, are always poor in chlorophyll and form a channel for conducting the products of assimilation away from the leaf by the stem. If a leaf of the liverwort is cut away from the foliar strand or leaf bundle and forms an approach to leptom, though it is not so specialized as the leptom of the higher Phanerogams. Associated with the leaf of the liverwort is a hydrom strand identical in character with those of the central strand of the stem, and no doubt serving to conduct water to or from the leaf according as the latter is acting as a transpiring or a water-absorbing organ. In a few cases the hydrom strand is continued into the cortex of the stem as a leaf-trace bundle (the anatomically demonstrable trace of the leaf in the stem). This in several cases runs vertically downwards for some distance in the outer cortex, and at some distance below the upper end of the leaf or leaf-band or star-shaped so as to present a large surface for the absorption of water from the adjacent cortical cells. In other cases the trace passes inwards and joins the central hydrom strand, so that the connected water-conducting system between stem and leaf is established.

In the highest family of mosses, Polytrichaceae, the differentiation of conducting tissue reaches a decidedly higher level. In addition to the water-conducting strand of the leaf, there is a well-developed tissue (leptom) inferred to be a conducting channel for organic substances. This leptom is not so highly differentiated as in the most advanced Laminariales, but shows some of the characters of sieve-tubes with great distinctness. Each leptom is an elongated living cell with nucleus and a thin layer of protoplasm lining the wall (fig. 1, K). The whole cavity of the cell is sometimes filled with water and the protoplasm is concentrated to the inner wall. The wall is usually very thin, and the protoplasm on artificial contraction forms a string-like process (a sieve-tube). A short distance from where the wall has been found. Associated with the leptom is a similar cell without swollen ends and with thicker cross-walls. Besides the hydron and leptom, and situated between them, is a tissue which perhaps serves to conduct soluble carbohydrates, and whose cells are ordinarily full of starch. It may be called amyloïd. The stem in this family falls into two divisions, an inner narrow portion (including rhizoids and scales), the rhizome, and a leafy aerial stem forming the direct appurtenant of the leaf. The leaf consists of a central midrib, several cells thick, and two wings, one cell thick. The midrib bears above a series of closely set, vertical, leaf-like organs of the leaf, in which the wings close in dry air so as to protect the assimilative and transpiring plates from excessive evaporation of water. The midrib has a strong band of stereome above and below. In its centre is a mass of bundle-sheath cells, each sheath encircling an amyloïd cell. This bundle is continued down into the cortex of the stem as a leaf-trace, and passing very slowly through the sclerenchymatous external cortex and the parenchymatous, starchy internal cortex to join the central cylinder. The latter has a central strand consisting of files of large hydroids, separated from one another by very thin walls, each file being separated from its neighbour by stout, dark-brown walls. This is probably homologous with the hydron of the liverwort, and may be called the hydroid. It is surrounded by (1) a thin-walled, smaller-celled hydrom mantle; (2) an amyloïd sheath; (3) a leptom mantle, interrupted here and there by strands of amyloïd, which are evidently formed by the conjoined bases of the leaf trace, each of which is composed of the same three tissues. As the aerial stem is traced down into the underground rhizome portion, these three component parts become transformed into the supporting system of the plant. As forming the bulk of the cylinder and its elements becoming mixed with thick-walled stercoids; at the same time this central hydrom-stereome strand becomes three-lobed, with deep furrows between the lobes. The inner of these three lobes of the stereome strand is the central mass by a few starchy cells, the remains of the amyloïd sheath. At the periphery of the lobes are some comparatively thin-walled living cells mixed with a few thin-walled hydroids, and often with strands of the leptom. Outside this are three arcs of large cells showing characters typical of the endodermis in a vascular plant; these are interrupted by strands of narrow, elongated, thick-walled cells, which send branches into the little brown scales borne by the rhizome. The sterile layer of the rhizome bears rhizoids, and its whole structure strikingly resembles that of the typical root of a vascular plant. In Catharina
**undulata** the central hydrom of the aerial stem is a loose tissue. This tissue is being filled up with thin-walled, starchy parenchyma. In *Dawsonia superba*, a large New Zealand moss, the hydroids of the central cylinder of the aerial stem are mixed with thick-walled sori creeds forming a hydrom-stereom strand somewhat similar to the cylinder in the Anthoceraceae.

The central hydrom strand in the sets of the sporogonium of most mosses has already been alluded to. Besides this there is usually a living conducting tissue, sometimes differentiated as leptosporangiate, sometimes another midrib, and a cortex externally by a more or less well-differentiated endodermis, abutting on an irregularly cylindrical lacuna; the latter separates the central conducting cylinder from the cortex of the sets, which, like the cortex of the gametophyte stem, is usually differentiated into an outer thick-walled stereom and an inner starchy parenchyma.

Frequently, also, a considerable differentiation of vegetative, tissue occurs. In the wall of the spore capsule itself, and in some of the higher forms a special assimilating and transpiring organelle is often constituted just below the capsule at the top of the sets, with a richly lacunar chlorophyllous parenchyma and stomata like those of the wall of the capsule in the Anthoceraceae liverworts. Thus the histological differentiation of the sporogonium of the higher mosses is one of considerable complexity; but there is here even less reason to suppose that these tissues have any homology (phylogenetic community of origin) with the similar ones met with in the higher plants.

The features of histological structure seen in the Bryophytic series are such as we should expect to be developed in response to the exigencies of increasing adaptation to terrestrial life on soil, and of increasing size of the plant-body. In the liverworts we find fixation of the thallus by water-absorbing rhizoids; in certain forms with a localized region of water-absorption the development of a primitive hydrom or water-conducting system; and in others with a rather massive type of thallus the differentiation of a special absorptive and transpiring system. In the more highly developed series, the mosses, this last division of labour takes the form of the differentiation of special assimilative organs, the leaves, commonly with a midrib containing elongated cells for the ready removal of the products of assimilation; and in the typical forms with a localized absorptive region, a well-developed hydrom in the axis of the plant, as well as similar hydrom strands in the leaf-midriils, are constantly met with. In higher forms the conducting strands of the leaves are continued downwards into the stem, and eventually come into connexion with the central hydrom cylinder, forming a complete cylindrical investment apparently distinct from the latter, and exhibiting a differentiation into hydrom, leptom, and epidermis, which closely parallels that found among the true vascular plants. Similar differentiation, differing in some details, takes place independently in the other generation, the sporogonium. The stereom of the moss is found mainly in the outer cortex of the stem and in the midrib of the leaf.

**Vascular Plants.**—In the Vascular Plants (Pteridophytes, i.e., ferns, horsetails, club mosses, &c., and Phanerogams or Flowering Plants) the main plant-body, that which we speak of in ordinary language as "the plant," is called the *sporophyte* because it bears the asexual reproductive organs or spores. The gametophyte, which bears the sexual organs, is either a free-living thallus corresponding in degree of differentiation with the lower liverworts, or it is a mass of cells which always remains enclosed in a spore and is parasitic upon the sporophyte.

The body of the sporophyte in the great majority of the vascular plants shows a considerable increase in complexity over that found in the gametophyte of Bryophytes. The principal new feature in the external conformation of the body is the acquirement of true root, the nearest approach to which in the lower forms we saw in the "rhizome" of Polytrichaceae. The primary root is a downward prolongation of the primary axis of the plant. From this, as well as from various parts of the shoot system, other roots may originate. The root differs from the shoot in the characters of its surface tissues, in the absence of the green assimilative pigment chlorophyll, in the arrangement of its vascular system and in the mode of growth at the apex, all features which are in direct relation to its normally subterranean life and its fixative and absorptive functions. Within the limits of the sporophyte generation the Pteridophytes and Phanerogams also differ from the Bryophytes in possessing special absorptive and transpiring organs, the leaves, though these organs are developed, as we have seen, in the gametophyte of many liverworts and of all the mosses.

The leaves, again, have special histological features adapted to the performance of their special functions.

On stem, root, and leaf, we can trace a three-fold division of tissue systems, a division of which there are indications among the lower plants, and which is the expression of the fundamental conditions of the evolution of a bulky differentiated plant-body. From the primitive uniform mass of undifferentiated assimilating cells, which we may conceive as the starting-point of differentiation, though such an undifferentiated body is only actually realized in the thallus of the lower Algae, there is, (1) on the one hand, a specialization of a surface layer regulating the immediate relations of the plant with its surroundings. In the typically submerged Algae and in submerged plants of every group this is the absorptive and the main assimilative layer, and may also by the production of mucilage be of use in the protection of the body in various ways. In the terrestrial plants it differs in the subterranean and subaerial parts, being in the former pre-eminently absorptive, and in the latter protective—provision at the same time being made for the gaseous interchange of oxygen and carbon dioxide necessary for respiration and feeding. This surface layer in the typically subaerial "shoot" of the sporophyte in Pteridophytes and Phanerogams is known as the *epidermis*, though the name is restricted by some writers, on account of developmental differences, to the surface layer of the shoot of Angiosperms, and by others extended to the surface layer of the whole plant in both these groups. On the other hand, we have (2) an internal differentiation of conducting tissue, the main features of which as seen in the gametophyte of Bryophytes have already been fully described. In the Vascular Plants this tissue is collectively known as the *vascular system*. The remaining tissue of the plant-body, a tissue that we must regard phylogenetically as the remnant of the undifferentiated tissue of the primitive thallus, but which often undergoes further differentiation of its own, the better to fulfill its characteristically vital functions for the whole plant, is known, from its peripheral position in relation to the primitive centrally conductive tissue, (3) the cortex. Besides absorption, assimilation, respiration, and protection there is another very important function for which provision has to be made in any plant-body of considerable size, especially when raised into the air, that of support. Special tissues (stereom) may be developed for this purpose in the cortex, or in immediate connexion with the conducting system, according to the varying needs of the particular type of plant-body. The important function of aeration, by which the inner living tissues of the bulky plant-body obtain the oxygen necessary for their respiration, is secured by the development of an extensive system of *intercellular spaces* communicating with the external air.

In relation to its characteristic function of protection, the epidermis, which, as above defined, consists of a single layer of cells has typically thickened and cuticularized outer walls, and diminishes the mechanical injury from without, and against the entry of smaller parasites, such as fungi and bacteria, but also especially to prevent the evaporation of water from within. The epidermis is often strengthened by *sporodermata* leading from the air outside to the system of intercellular spaces below. Each stoma is surrounded by a pair of peculiarly modified epidermal cells. The stomata are thus the entry of air to the leaf, according to the need for respiration. The structure of the stomata of the sporophyte of vascular plants is fundamentally the same as that of the stomata on the sporogonium of the true mosses and of the liverwort *Anthoceros*. Stomata are often situated at the bottom of pits in the surface of the leaf. This arrangement is a method of checking transpiration by creating a still atmosphere above the pore of the stoma, so that water vapour collects in it and diminishes the flow of water from the leaf. As a last detail of structure, which is extremely various in its details, is found especially, as we should expect, in plants which have to economize their water...
supply. The stomata serve for all gaseous interchange between the plant and the surrounding air. The guard-cells contain chlorophyll and are able to perform the functions of the photosynthetic apparatus, thus permitting the leaf to function as a tissue for water storage. Sometimes the epidermis is considerably more developed by tangential division of its cells, forming a many-layered water-tissue. This is found especially in plants which pass the day exposed and in those capable of retaining water when not in use. Such water-tissue usually forms a gaseous conducting system between the surface and the mesophyll, but in some cases, as in the lotus, the water-tissue is missing.

The water stored in such a tissue supplies the immediate need of the transpiring cells and prevents the injury which would result from their drying up. The water may be lost through transpiration by the supply coming from the roots. The water stored in such a tissue supplies the immediate need of the transpiring cells and prevents the injury which would result from their drying up. The water may be lost through transpiration by the supply coming from the roots.

The epidermis of a very large number of species bears hairs of various kinds. The simplest type consists simply of a single elongated cell, projecting from the surface. Other hairs consist of a chain of cells; others, again, are branched in various ways; while yet others have the form of a flat plate of cells placed parallel to the leaf surface and containing large air-bubbles. The cells of these hairs may have a thick semi-transparent wall, or they may simply contain air. A very common function of hairs is to diminish transpiration, by creating a still atmosphere between them, as in the case of the sunken stomata already mentioned. Blanket hairs help in the distribution of water to the surrounding atmosphere, and in the case of annual plants, in the protection of the young shoot from injury. Sometimes a hair is so placed as to form a projection or beehive, in situations where the plant is seldom watered or where the air is very dry, easily breaking off when touched. The sharp, broken end penetrates the skin, and into the slight wound thus formed the fluid passes, as a form of contamination.

Mention may be made here of a class of epidermal organ, the hydathodes, the wide distribution and variety of which have been revealed by recent research. These are special organs, which are usually situated on the lower side of the leaf, and consist of a group of cells, or rather of air-bubbles, so numerous and so near each other that they form a network of fine intercellular spaces, which are normally filled with water and debouch on one or more intercellular cavities below the epidermis. Above each cavity is situated a so-called water-stoma, a double or quadrupleivalve, which, when closed, excludes the air from the water-tissue, and when open, permits a free passage of water to the atmosphere below. Hydathodes are of common occurrence in the leaves of aquatic plants. The cells of these hairs may have a thick semi-transparent wall, or they may simply contain air. A very common function of hairs is to diminish transpiration, by creating a still atmosphere between them, as in the case of the sunken stomata already mentioned. Blanket hairs help in the distribution of water to the surrounding atmosphere, and in the case of annual plants, in the protection of the young shoot from injury. Sometimes a hair is so placed as to form a projection or beehive, in situations where the plant is seldom watered or where the air is very dry, easily breaking off when touched. The sharp, broken end penetrates the skin, and into the slight wound thus formed the fluid passes, as a form of contamination.

Epidermis or Surface Layer.

The surface layer of the root, sometimes included under the term epidermis, may be of circinate or subcircinate form in front of the leaf. In correspondence with its water-absorbing function it is not cuticularized, but remains usually thin-walled; the absorbing surface is increased by its being provided with root-hairs or rhizoids, which are borne firmly to particles of soil, thus at once fixing the root firmly in the soil, and enabling the hair to absorb readily the thin films of water ordinarily surrounding the particles (fig. 1, U). The root-hair ends become free from the epidermis and for the most part are directed inwards towards the outer surface, thus facilitating the passage of the apex as it is pushed between the particles of soil.

Cortex.

The cortex, as has been said, is in its origin the remains of the primitive leaves which originally covered the plant after differentiation of the surface layer and the conducting system. It consists primarily of the living parenchyma; its differentiation may be extremely varied, since in the complex bodies of the higher plants its functions are numerous. In all green plants which have a special protective epidermis, the cortex of the shoot has to perform the primitive fundamental function of carbon assimilation. The leafy shoot this function is mainly localized in the cortical tissue of the leaves, known as mesophyll, Mesophyll, which is essentially a parenchymatous tissue containing chloroplasts, and is penetrated by a system of intercellular spaces so that the surfaces of the assimilating cells are brought into contact with air to as large an extent as possible, in order to facilitate gaseous interchange between the assimilating cells and the atmosphere. At the same time the cells of the mesophyll are transpiring cells, i.e., the evaporation of water from the leaf goes on from them into the intercellular spaces. The only pathways for the gases which thus pass between the cells of the mesophyll and the outside air are the stomata. A land plant has nearly always to protect itself against over-transpiration, and for this reason the stomata of the typical dorsiventral leaf (fig. 2, A), which has distinct upper and lower faces, are placed mainly or exclusively on the lower side of the leaf, whereas the water vapour that escapes from them, being lighter than air, cannot pass away from the surface of the leaf, but remains in contact with it and thus tends to check further transpiration. The stoma are distributed over the entire shoot, and the main transpiring system of intercellular spaces which is found in the loosely arranged mesophyll (spongy tissue) on that side. This is the main transpiring tissue, and is protected from direct illumination and consequent too great evaporation. The main assimilating tissue, on the other hand, is under the upper epidermis, where it is well illuminated, and consists of oblong cells densely packed with chloroplasts and with their long axes perpendicular to the surface (palisade tissue). The intercellular spaces are here of very narrow channels between the palisade cells. Leaves whose blades are normally held in a vertical position possess palisade tissue and stomata on both sides (isobilateral leaves) (fig. 2, B), since there is no difference in the illumination and other external conditions, while those which are cylindrical or of similar shape (centric leaves) have it all round. The leaves of shade plants have little or no differentiation of palisade tissue. In fleshy leaves which contain a great bulk of tissue in relation to their chlorophyll content, the central mesophyll contains little or no chlorophyll and acts as watertissue. The cortex of a young stem is usually green, and plays a more or less important part in the assimilative function. It also always possesses a well-developed lacunar system communicating with the external air through stomata (in the young stem) or lenticels (see below). This lacunar system not only enables the cells of the cortex itself to respire, but also forms channels through which air can pass to the deeper-laying tissues. The cortex of the older stem of the root frequently acts as a reserve store-house for food, and at the same time is practically a storehouse for sap, and in this latter capacity it is often found to be thickly invested in providing the stromes of the plant. In the leaf-blade this sometimes appears as a layer of thickened subepidermal cells, the hypoder, often also as subepidermal bundles of sclerenchymatous fibres, or as similar bundles extending right across the leaf from one epidermis to the other and thus acting as struts. Isolated cells (idioleasts), thickened in various ways, are not uncommonly supporting the tissues of the leaf. In the larger veins of the leaf, the cortex at the ends of veins, and also often the vascular system is largely in providing the stromes of the plant. In the leaf-blade this sometimes appears as a layer of thickened subepidermal cells, the hypoder, often also as subepidermal bundles of sclerenchymatous fibres, or as similar bundles extending right across the leaf from one epidermis to the other and thus acting as struts. Isolated cells (idioleasts), thickened in various ways, are not uncommonly supporting the tissues of the leaf. In the larger veins of the leaf, the cortex at the ends of veins, and also often the vascular system is largely in providing the stromes of the plant. In the leaf-blade this sometimes appears as a layer of thickened subepidermal cells, the hypoder, often also as subepidermal bundles of sclerenchymatous fibres, or as similar bundles extending right across the leaf from one epidermis to the other and thus acting as struts. Isolated cells (idioleasts), thickened in various ways, are not uncommonly supporting the tissues of the leaf. In the larger veins of the leaf, the cortex at the ends of veins, and also often the vascular system is largely in providing the stromes of the plant. In the leaf-blade this sometimes appears as a layer of thickened subepidermal cells, the hypoder, often also as subepidermal bundles of sclerenchymatous fibres, or as similar bundles extending right across the leaf from one epidermis to the other and thus acting as struts.
The innermost layer of the cortex, abutting on the central cylinder of the plant, is the periderm, or bark. The innermost layer of the periderm is the phellem, and is often differentiated. In the leaf-blade it forms the tissue consisting of parenchymatous sheaths to the bundles. The cells of these sheaths are often distinctly thicker than the xylem, and are usually chlorophyll-containing and little or no chlorophyll. Occasionally, however, they are particularly rich in chloroplasts. These bundle sheaths are important in the conduction of carbohydrates away from the assimilating cells of the leaf. In the stem (particularly in Pteridophytes), and universally in the root, the phellem is developed as an endodermis (see below). In other cases it does not differ histologically from the parenchymatous cells of the xylem and phloem. The outer layer of the phellem is distinguished by containing particularly abundant starch, in which case it is known as a starch sheath.

It is only in its characters common to the two highest groups of plants, the Pteridophytes and Phanerogams, is the 

**Vascular System.**

**ANATOMY**

Furthermore, an important feature of the Pteridophytes is the construction of a body in which the vascular cylinder is advanced; that is, it is surrounded by a cortex whose tissues, in the primary axis of the plant among Pteridophytes and many Phanerogams, is a double cylinder of xylem and phloem. The xylem is always associated in the form of a cylinder (stele), with xylem occupying the centre, and the phloem (in the upward-growing part or primary stem) forming a mantle at the periphery (fig. 4).

<ANATOMY>

**ANATOMY**

However, the peripheral mantle of phloem is interrupted, the xylem coming to the surface of the cylinder along (usually) two or (sometimes) more vertical lines. Such an arrangement of vascular tissue is called radial, and is characteristic of all roots (figs. 3 and 10). The cylinder is surrounded by a mantle of one or more layers of parenchymatous cells, the pericycle, and the xylem is generally considered to be the phloem in the case of the Pteridophytes. The pericycle has been shown to be an extremely specialized and peculiarly differentiated group. Furthermore, both the hydrom and leptom of Pteridophytes have marked peculiarities to which no parallel is to be found among the Phanerogams. In the latter, the xylem and phloem are developed in a continuous system of the Pteridophytes has had an entirely separate evolution. All the surviving forms, however, have a completely established double system with the specific characters allied to, and either thin-walled or thick-walled with lignified (woody) spiral (fig. 1, p.)

that of the amphiphloic haplostele, is maintained throughout the adult stem (Lindsey). In the majority of ferns, at a higher level, after the stele has increased greatly in diameter, a large-celled true pith or medulla, resembling the cortex in its characters, and quite distinct from conjunctive, from which it is separated by an internal endodermis, appears in the centre. These successive new tissues, appearing in the centre of the stele, as the stem of a higher fern is traced upwards from its first formed parts, are all in continuity with the respective corresponding external tissues at the point of origin of each leaf trace (see below). Where internal phloem in present this is separated from the internal endodermis by an endocycle or "internal pericycle," as it is sometimes called, and from the xylem by an internal mesocycle—these two layers, together with the outer mesocycle and pericycle, constituting the conjunctive tissue of the new hollow cylindrical stele. The conjunctive frequently forms a connected whole with bands of axis. The type of siphonostele characteristic of many ferns, in which are found internal phloem, and an internal endodermis separating the vascular conjunctive from the pith, is known as a solenostele. The solenostele of the ferns is broken by the departure of each leaf-bundle, the outer and inner endodermis joining so that the stele becomes horsehoe-shaped and the cortex continuous with the pith (fig. 6). Such a break is known as a leaf-gap. A little above the departure of the leaf-bundle the stele again closes up, only to be again broken by the departure of the next leaf-bundle. Where the leaves are crowded, a given leaf-gap is not closed before the next ones appear, and the solenostele thus becomes split up into a number of segments, sometimes band-shaped or semilunar, sometimes isodiometric in cross-section (fig. 7). In the latter case each segment of the solenostele frequently resembles a haplostele, the segments of inner endodermis, pericycle, phloem and mesocycle joining with the corresponding outer segments to form a nearly concentric structure. For this reason a stem in which the vascular system has this type of structure is used to be spoken of as polystelic, the term "stele" being transferred from the primary central cylinder of the axis and applied to the vascular strand just described. In this use the term holds, on account of its morphological value, and it is better to call such a segment of a broken-up stele a meristele, the whole solenostele with overlapping leaf-gaps being called a dictyostele. The splitting up of the vascular tube into separate strands does not depend wholly upon the occurrence of leaf-gaps. In some forms other gaps (perforations) appear in the vascular tube placing the pith and cortex in communication.
In other cases the leaf-gaps are very broad and long, and the meristems sometimes produced to a comparatively slender strand, while there is present in each gap a number of partly reduced vascular strands, some of which run out to the leaf, while others form cross-connections between these "leaf-trace" strands and also with the main xylem mass. These leaf-traces may be resolved into a number of fine threads. Such a structure may be spoken of as a dissected dictyostele.

In some solenostelic ferns, and in many dictyostelic ones additional vascular strands are often present, which run out to the sides of the primary vascular tube. They usually run freely in the pith and join the primary tube in the neighbourhood of the leaf-gaps. Set beside a complete internal vascular cylinder, having the same structure as the older and connecting it, occurs in the pith, and others may appear, internal to the first (Matonia, Saccodendron). Juncions of the first internal cylinder and the outer primary at the leaf-gaps, and of the second internal cylinder with the first, make up the "primary-neighbourhood" (fig. 8). In dictyostelic ferns similar internal (dicyostelic) cylinders are found in some forms, and occasionally a large solenostele was described in several forms of the higher mosses. In such cases the vascular system is said to be poly cyclic in contrast with the ordinary monostele condition. These internal strands or cylinders are to be regarded as peculiar types of elaboration of the leaf-trace system, and can be drawn upon when the water supply from the root is deficient.

The vascular supply of the leaf (leaf-trace) consists of a single strand only in the haplostele and some of the more peculiar sphenostele forms. In the "microphyllous" groups of Pteridophytes (Lycopodiales and Equisetaceae) in which large fronds are attached to the stem, the single bundle destined for each leaf is often a "primary" one, whose departure causes no disturbance in the cauleine stele. In the "megaphyllous" forms, on the other hand, (Ferns) whose leaves are large relatively to the stem, the departure of the corresponding large trace causes a gap (leaf-gap) in the vascular cylinder, as already described. In the haplostele ferns the leaf-trace appears as a single strand with a tendency to assume the shape of a horse-shoe on cross-section, and this type is also found in the more primitive solenostele types. In the more highly developed forms, as already indicated, the leaf-trace is split up into a number of strands which leave the base and sides of the leaf-gap independently. In the 10 fern families, including the Filicales, the monostele may vary from the monostele to the xerostele, or toward the pericycle, and though usually reducible to the outline of the primitive "horse-shoe," more or less elaborated, they may in some of the complex polystelic ferns (Marattiaceae) be arranged in several concentric circles, thus indicating the arrangement of strands formed in the stem. The evolution of the vascular structure of the petiole in the higher ferns is strikingly parallel with that of the stelar type, except in some few special circumstances for water-storage which can be drawn upon when the water supply from the root is deficient.

There is good reason to believe that the haplostele is primitive in the evolution of the vascular system. It is found in most of the Pteridophytes which we have other reasons for regarding as primitive. The so-called "protophyllous," or "hexarch," type is found, as we have seen, in the independently developed primitive conducting system of the moss-stem. This type of stem is therefore often spoken of as "prophyllous." In the higher ferns the haplostele or solenostele developed independently from (Marattiaceae) to be soleno-
stelic and in dictyostelic forms. In the formation of the stem of any fern characterized in the adult condition by one of the more advanced types of vascular structure all stages of increase in complexity from the haplostele of the first-formed stem to the particular condition characteristic of the adult stem are gradually passed through by a series of changes exactly parallel with those which took place in the stem of the fern. These changes, including the comparison of the adult forms, must have taken place in the evolution of the race. There is no more striking case in the plant-kingdom of the parallel between ontogeny (development of the individual) and phylogeny (development of the race) so well known in many groups of animals.

The stele of most Lycopsids is a more or less modified protostele, but in the genus Lycopodium a peculiar arrangement of the xylem and phloem is found, in which the xylem is confined to a peripheral mantle of tissue, forms bands running across the stele and alternating with similar bands of xylem (fig. 12). In Selaginella the stelar system shows that the primary xylem is confined to the cortex in some forms, and in others in the cortex and the bundle, while in the mature plant the endodermis contains the "comet", which at first lies on the surface of the primary stele, but eventually, at a higher level separate from it and form distinct "secondary" stelar rings around the primary one. Similar cords may be divided on, and may separate from, these secondary stelar, thus giving rise to a series of stelar arranged in a single file (fig. 11). In the creeping stem of one species (S. Lysilii) a polycyclic solenostele is formed, the leaf-trace descending from the xylem in the outer tubular stele, however, are formed by the departure of aerial branch-traces, instead of leaf-traces as in the ferns. The first formed portion of the stem in all species of Selaginella which have been investigated is a protostele. The investigation of Equisetum is of a peculiar type whose relations are not completely clear. It consists of a ring of endarch collateral bundles, which in the stem of the prophyll type of each is a leaf-trace, while the metaxytem consisting of five or six strands forms a quite distinct cauleine system. All the metaxytem joins at the nodes into a complete ring of xylem. The whole stele may be regarded as an exarch collateral one, although it is clear that there is an internal endodermis in addition, separating the bundles from the pith; while in other cases each bundle possesses a separate endodermis surrounding it. At the nodes the relation of the xylem to the phloem passes to the xylem, the stele thus becoming often acheneiform. It is probable that this type of stelar is a modification of a primitive protoste, in which the main mass of stelar has undergone much reduced and incidentally separated from the leaf-trace system.

During recent years a number of fossil (Carboniferous and Permian) plants have been very thoroughly investigated in the light of modern Cycles, though, and as a result it has become clear that in those times a large series of plants existed intermediate in structure between the modern ferns and the modern Gymnosperms (especially Cycads).

Stelar System of Cycads.

The greater part of the stelar system of Cycads has been applied. We now know that many at least of the Cycadofilices bore seeds, of a type much more complex than that of any modern seed plants, and in some cases approximating to the seeds of existing gymnosperms. Of these the probable stelar type leading from the primitive fern-protoste to the type of sphenostele characteristic of the Cycads which appears in essentials in all the Spermatophyta, is in this transition appear to have been (1) disappearance of the pith, (2) the stelar and replacement by pith, leading to the survival of a number of (mesarch) collateral bundles (see below) at the periphery of the stem. Passage from mesarch to endarch stages of these bundles correlated with a great increase in secondary thickening of the stele.

The leaves of the more primitive members of this series were entirely fern-like and possessed a fern-like vascular strand; while in the later series, which include the living cycads, the pith, although unaffected by secondary thickening, are mesarch, while those of the stem-stele have become endarch. Besides the types forming this series, there are a number of others (Medulloses and allied forms) which show, however, very complex, types of stelar structure, in some cases polyoste, whose origin and relationship with the simpler and better known types is frequently obscure. Among the existing families of Spermatophyta, the type of vascular system conforms on the whole with that of the other cycads. The xylem and phloem are often found (e.g. indications of polyoste, frequent occurrence of extrastelar concentric bundles, "anomalous" secondary thickening, "protosteles") are varied and complex, and in many cases very complex.

The typical structure of the vascular cylinder of the adult primary stem in the Gymnosperms and Dicotyledons is, like that in the ferns, a monocyclic structure enclosing a central parenchymatous pith. But, unlike the ferns, there is in the seed-plants no internal phloem (except as a special development in certain families) and no internal endodermis. The xylem and phloem also, rarely form perfectly continuous layers as they do in a solenoste fern. The vascular tissue is typically separable into distinct collateral bundles, the xylem of which is usually wedge-shaped in cross-section with the protoxylem elements at the inner extremity, while the phloem forms a band on the outer side of the xylem, and separated from it by a band of collateral tissue (figs. 5, 6). These vascular bundles are often arranged by bands of conjunctive tissues called primary medullary rays, which may be quite narrow or of considerable width. When the pith is large celled, the xylems of the bundles are separated from it by a layer of parenchymatous cortex. A similar layer, the pericycle, separates the phloem from the cortex. The inner layer of the cortex (phloetema) may form a well-marked endodermis, or differ in other ways from the rest of the cortex. The outer layers of the xylem and pericycle are usually of parts of one tissue system, the external conjunctive, and are normally topographically separable. The external conjunctive is usually a living comparatively small-celled tissue, whose cells are considerably smaller in diameter than those of the xylem and phloem, and some workers believe that the endodermis may contain abundant starch. Certain regions of it, particularly the whole or part of the pericycle, but sometimes also the endodermis, are typically converted into thick-walled cells (e.g. coniferous trees), and so called "secondary meristems" (see p. 741) to arise in the external conjunctive.
Most of the collateral bundles of this siphonostele type of phloem are leaf-trace bundles, i.e., they are transversely cut from any given point till they are found to pass out of the cylinder, travel through the cortex of the stem and enter a leaf. The remaining bundles (compensation bundles) which go to make up the cylinder are such as have been described from the leaves above and will, after joining with others similarly given off, themselves form the traces of leaves situated at a higher level on the stem. Purely cauline vascular strands (i.e., confined to the stem) such as are found in the dicotyledons of ferns are rare in the flowering plants. The leaf trace of any given leaf rarely consists of a single bundle only (unifascicular); the number of bundles of any given trace is always odd; they may either be situated all together before they leave the stipe or they may be distributed within the internodes. The median bundles of the trace are typically the largest, and at any given level of the stem the bundles destined for the next leaf above are as a whole larger than those which are destined for the levels below. Leaf-traces after junction with other similar bundles, is the great characteristic of the stem-leaf of flowering plants. These collateral bundles are obviously highly individualized. The external conjunctive tissue is often arranged in relation to each bundle separately and referred to, being often confined to the bands of pericyclic tissue abutting on the phloem of each bundle, while the cortex and pith frequently form rays in the intervals between the adjacent bundles.

In some cases this individualization is carried further, the cortex and pith becoming continuous between the bundles which appear as isolated strands embedded in a general ground-tissue. Each bundle has its own investment of tissue, corresponding to the external conjunctive, and now called periderm. The bundles sometimes keep their arrangement in a ring corresponding with the stipe, though the continuous cylinder no longer exists (species of Ranunculaceae). This condition is known as astyl. In some astic stems (Nymphaeaceae) the number of bundles is greatly increased and they are scattered throughout the ground tissue. A "polystelic" condition arises in some members of this order by the association of collateral bundles in common centres. A similar phenomenon is seen in two widely separated genera of flowering plants: Primula & Aroida and Asparagus (Liliaceae). The monocotyledons, one of the primary divisions of angiosperms, is the monocots, which typically possess large leaves with broad sheathing bases containing a very great number of bundles. This result is due to the number of bundles present at any given level of the stem being enormously increased. These bundles are arranged in a definite though not superficially obvious order through the conjunctive tissue of the stem, which occupies nearly the whole diameter, and the stem finally being reduced to a very narrow layer, or disappearing altogether (fig. 3). The mass of conjunctive tissue is often referred to as a "ground-tissue" and round each bundle there is a "periderm" which is often fibrous (fig. 16). It is possible to suppose that this condition is derived from the astyle type, but the evidence on the whole leads to the conclusion that it has arisen by an increase in the number of the bundles within the stipe, the individuality of the bundle asserting itself after its escape from the original bundle-ring of the primitive cylinder.

In the stems of many water-plants various stages of reduction of the vascular system, especially of the xylem, are met with, and very often this reduction leads to the formation of a compact stele in which the individuality of the separate bundles may be suppressed, so that a closed cylinder of xylem is formed, the phloem being generally unReduced Haplostele Type.

In other cases the reduction goes much further, till the endodermis eventually comes to surround nothing but an intercellular channel formed in place of the stelar tissue.

In the blade of a typical leaf of a vascular plant—essentially a siphonostele—there is a single conducting tissue in the form of a number of separate, usually branching and anastomosing strands. These, with their associated stelem, form a kind of framework which is of great importance in supporting the stem. In ferns, especially in the mesophyll of the leaf, it is provided with a number of channels, penetrating every part of the leaf, between which water and dissolved salts are conveyed to, and elaborated food-substances from, the mesophyll cells. The bundle-system is of course continuous with that of the petiole and stem. The leaf-bundles are always collateral (the phloem being turned downwards and the xylem upwards), even in Ferns, where the petiolar strands are concentric, and they have the ordinary meso- and pericycle of the collateral bundle. The latter is often ceriferous, especially opposite the phloem, and to a less extent opposite the xylem, as in the Stem. As a bundle is traced towards its blind termination in the mesophyll the peridermic stelem first disappears, the sieve-tubes of the phloem are replaced by narrow elongated parenchyma cells, which soon die out, and the bundle ends with a strand of tracheids covered by the phloematic sheath.

The structure of the stele of the primary root as it is found in most Pteridophytes and many Phanerogams has already been described. The stele is acritical of all root-stems, which have in essential points a remarkably uniform structure throughout the vascular plants, a fact not so largely dependent on the very uniform conditions under which they live. While the stele of the primary root in both Gymnosperms and Angiosperms is usually diarch or tetrarch, the large primary root-stems of many adventitious roots are frequently polyarch, sometimes with a very large number of protoxylemas. Such a stele seldom has the centre filled up with xylem, this being replaced by a large-celled pith, so that a siphonostelic structure is acquired (fig. 15). Sometimes, however, the centre of a bulky root-stem has strands of metaxylem (to which may be added strands of meta-pith), scattered through it, the interstices being filled with conjunctive. The conjunctive of a root-stele possessing a pith is often ceriferous between the pith and the pericycle. Sometimes the central portion of the root-stem becomes a "polystelic" structure.

In certain families of Angiosperms a peculiar tissue, called laticiferous tissue is met with. This takes the form of long, usually

[Fig. 17.—Transverse section of the stele of the stem of a water-plant (Naias); l. intercellular channel representing xylem; ph. phloem; e. endodermis.]

[Fig. 18.—Vertical section of a Palm stem, showing the vascular bundles, Ph. curvature inwards and then outwards.]
ANATOMY

PLANTS 739

richly branched tubes which penetrate the other tissues of the plant mainly in a longitudinal direction. They possess a delicate layer of protoplasm, with numerous small nuclei lining the walls, while the interior of the tube (corresponding with the cell-contents) contains a fluid called latex, consisting of an emulsion of fine granules and droplets of varying substances suspended in a watery medium in which various other substances (salts, sugars, rubber-producers, tannins, alkaloids and various enzymes) are dissolved. Of the suspended substances, grains of cascaihouc, drops of resin and oil, proteid crystals and starch grains may be mentioned. Of this varied mixture of substances some are undoubtedly plastic (i.e., of use in constructing new plant-tissue), others are apparently end-products of metabolism, in other words secreta, though they are not actually cast out from the plant-body. The relation of the laticiferous tissue to the assimilating cells under which they often end and the fact that where this tissue is richly developed the conducting parenchyma of the bundles, and sometimes also the sieve-tubes, are poorly developed as well as various other facts, point to the conclusion that the laticiferous system has an important function in conducting plastic substances, in addition to acting as an excretory reservoir. As a secondary function we may recognize, in certain cases, the power of closing wounds, which results from the rapid coagulation of exuded latex in contact with the air. The use of certain plants as rubber-producers (notably Hevea brasiliensi, the Para rubber-tree) depends on this property. The trees are regularly tapped and the coagulated latex which exudes is collected and worked up into rubber. Opium is obtained from the latex of the opium poppy (Papaver somniferum), which contains the alkaloid morphine.

Laticiferous tissue is of two kinds: (1) laticiferous cells (coenocytes) (fig. 19) which branch but do not anastomose, and the apices of which keep pace in their growth with that of the other tissues of the plant (Apocynaceae, most Euphorbiaceae, &c.); (2) laticiferous vessels (fig. 20) which are formed from rows of meristematic cells, the walls separating the cells breaking down, so that a network of laticiferous tubes arises (Papaveraceae, Hevea, &c.). In some cases (Allium, Convolvulaceae, &c.) rows of cells with latex-like contents occur, but the walls separating the individual cells do not break down.

The body of a vascular plant is developed in the first place by repeated division of the fertilized egg and the growth of the products of division. The body thus formed is called the embryo, and this develops into the adult plant, not by continued growth of all its parts as in an animal, but by localization of the regions of cell-division and growth, such a localized region being called a growing-point. This localization takes place first at the two free ends of the primary axis, the descending part of which is the primary root, and the ascending primary shoot. Later, the axis branches by the formation of new growing-points, and in this way the complex system of axes forming the body of the ordinary vascular plant is built up. In the flowering plants the embryo, after developing up to a certain point, stops growing and rests, enclosed within the seed. It is only on germination of the latter that the development of the embryo into the free plant is begun. In the Pteridophytes, on the other hand, development from the egg is continuous.

The triple division of tissues is laid down in most cases at a very early period of development—in the flowering plants usually before the resting stage is reached. In many Pteridophytes the first leaf is formed very early in the embryonic stage, and the first root also is developed at its base, usually becoming continuous with the cylinder of the root; the strand of the second leaf is formed in a similar way and runs down to join that of the first, so that the stem is formed by the joined bases of the leaf-traces. In other cases, however, a continuous primitive stele is developed, extending from the primary stem to the primary root, the leaf-traces arising later. This is correlated with the comparatively late formation and small development of the first leaves. The evidence scarcely admits of a decision as to which of these methods is to be regarded as primitive in descent. In the seed-forming plants (Phanerogams) one or more primary leaves (cotyledons) are already formed in the resting embryo. In cases where the development of the embryo is advanced at the resting period, traces run from the cotyledons and determine the symmetry of the stele of the primitive axis, the upper part of which often shows stem-structure, in some respects at least, and is called the hypocotylar stem or hypocotyl, while the lower part is the primary root.

(racicle). In other cases the root structure of the stele continues up to the cotyledonary node, though the hypocotyl is still to be distinguished from the primary root by the character of its epidermis. On germination of the seed the radicle first grows out, increasing in size as a whole, and soon adding to its tissues by cell division at its apical growing-point. The hypocotyl usually elongates, by its cells increasing very greatly in the longitudinal direction both in number and size, so that the cotyledons are raised into the air as the first foliage-leaves. Further growth in length of the stem is then confined to the apical growing point situated between the cotyledons. In other cases this growing-point becomes active once, there being little or no elongation of the hypocotyl and the cotyledon or cotyledons remaining in the seed.

The structure of the growing-points or apical meristems varies much in different cases. In most Pteridophytes there is a single large apical cell at the end of each stem and root axis. This usually has the form of a tetrahedron, with its base occupying the surface of the body of the axis and its apex pointing towards the interior. In the stem, segments are successively cut off from the sides of the tetrahedron, and by their subsequent division the body of the stem is produced. In the root exactly the same thing occurs, but segments are cut off also from the base of the tetrahedron, and by the division of these the root-cap is formed (fig. 21). In both stem and root early walls separate the cortex from the stele. The epidermis in the stem and the surface layer of the root soon becomes differentiated from the underlying tissue. In some Pteridophytes the apical cell is wedge-shaped, in others prismatic; in the latter case segments are cut off from the end of the prism turned towards the body of the stem. In other cases, again, a group of two or four prismatic cells takes the place of the apical cell. Segments are then cut off
from the outer sides of these initial cells. In most of the Phanerogams the apical (or primary) meristem, instead of consisting of a single apical cell or a group of initials, is stratified—i.e. there is the differentiation of leaf-bundles, which typically begins at the base of the leaf and extends upwards into the leaf and downwards into the root, is the first phenomenon, the first development, in the life of a plant. The spaces intervening between adjacent bundles, and forming the cylinder, are never occupied by small-celled tissue; the cylinder is composed of small-celled tissue only. The differentiations of the leaf-bundles are, in fact, determined by the cylinder, which is the primary cortical meristem of the stem, and a formation of leaf-tissue, and is seen at a higher level than the formation of a stellate meristem. The latter is produced (except in cases of complete stellate) when a cylinder is never formed) after a number of leaf-traces have appeared on different sides of the stem, so as to form a cylinder as the primary transverse section, the spaces intervening between adjacent bundles becoming bridged by small-celled tissue closing the cylinder. In this tissue fresh bundles may become differentiated, and what remains of the cylinder the cylinder is formed by the tissues (the fully-differentiated) which exist which are intermediate between the two extreme types described. In these the stellate becomes obvious in transverse section at about the same time as that at which the first leaf-traces are developed. Where a large-celled pith is developed this often becomes obvious very early, and in some cases it appears to have separate initials situated below those of the hollow vascular cylinder. In some cases where there is an apparent pith near the apex, this is really the young pith, the distinction between the stellate and cortical initials, if it exists, being, as is so often the case, impossible to make out. The young tissue of the stellate cylinder, in the cases of the modified phloem characteristically of the dicotyledonous stem, differs from the adjoining pith and cortex in its narrow elongated cells, a difference produced by the stopping of transverse and the increased frequency of longitudinal divisions. This is thus the opposite case in the young vascular bundles to a desmogen strands). The protoxylem and phloem are developed a few cells from the inner and outer margins respectively of the desmogen strand, the desmogen tissue is left over giving rise to the endodermis of the bundle. Differentiation of the xylem progresses outwards, of the phloem inwards, but the two tissues never meet in the centre. Sometimes development steps altogether, and a layer of undifferentiated parenchyma (the medullary) is left between them; or if it may continue increased, the central cells keeping pace by their tangential division with the differentiation of tissue on each side. In this case the formation of the primary bundle passes straight over into the formation of secondary tissue by a cumbium, and no line can be drawn between the two processes. The differentiation of the stellar stellate, which usually takes the form of a sclerized pericycle, and may extend to the xylem and rays, takes place in more cases later than the formation of the primary vascular strand. In the very frequent cases where the bundles have considerable individuity, the hitherto "pericyclic" cap very clearly has a common origin from the vascular strand of the root. It is composed of cells, in such cases it is part of the perisperm or sheath of elongated narrow-celled tissue surrounding the individual bundle. The separation of layers in the apical meristem of the root is usually very much more obvious than in that of the stem. The outermost is the epidermis, which gives rise to the root-cap, and in Dicotyledons to the piliferous layer as well. The periderm, one cell thick at the apex, produces the cortex, to which the piliferous layer belongs, which is nearly always sharply separated from the periderm, gives rise to the vascular cylinder. In a few cases the boundaries of the different layers are not traceable. The protoxylem and the phloem strands are developed alternately, just within the outer limit of the young cylinder. The differentiation of metaxylem follows according to the type of root-stele, and, finally, any stromat there may be is developed. Differentiation is very much more rapid—small-celled cases are completely formed much nearer to the apex, than is the case in the stem. This is owing to the elongating region (in which protoxylem and protophloem alone are differentiated) being very much shorter than in the stem. The young stellite root-hairs grow out from the cells of the piliferous layer immediately behind the elongating region. The branches of the stem arise by multiplication of the cells of the epidermis and cortex at a given spot, giving rise to a proliferance, at the end of which an apical meristem is established. The vascular system is connected in various ways with that of the parent axis by the differentiation of bundle-connexions across the axis, that of the latter. This is known as adventitious branching. This is the origin of adventitious branches in the root, on the other hand, the origin of branches is endogenous. The cells of the pericycle, usually opposite a protoxylem strand, divide tangentially and give rise to a new growing-point. The new root thus laid down burrows through the cortex of the mother-root and finally emerges into the soil. The connections of its stellite with that of the parent axis are made across the pericycle of the latter. These never in connexion with the cortex of the parent, but with its pericycle. Adventitious root-branches develop from the stem, usually take origin in the pericycle, but sometimes from other parts of the conjunctive.

In most of the existing Pteridophytes, in the Monocotyledons, and in annual plants among the Dicotyledons, there is no further growth of much structural importance in the secondary tissues after differentiation from the primary meristems. But in nearly all perennial Dicotyledons, in all dicotyledonous and gymnosperous trees and shrubs,

Secondary Tissues.
and in fossil Pteridophytes belonging to all the great groups, certain layers of cells remain meristematic among the permanent tissues, or after passing through a resting stage reacquire meristematic properties, and give rise to secondary tissues. Such meristematic layers are called secondary meristems. There are two types of secondary meristems, the cambium and the phloemogen.

The formation of secondary tissues is a characteristic feature of woody plants, to whatever class they belong. Every great group or phylum of vascular plants, when it has become dominant in the vegetation of the world, has produced members with the tree habit arising by the formation of a thick woody trunk, in most cases by the activity of a cambium.

The cambium in the typical case, which is by far the most frequent, continues the primary differentiation of xylem and phloem in the desmogen strand (see above), or arises in the resting meristems of dicotyledons. In both cases the cambium consists of a number of horizontal cells, or fibers, which are alternately xylem and phloem. A mother-cell of the xylem may, in the most advanced types of Dicotyledons, give rise to—(1) a tracheid; (2) a segment of a vessel; (3) a xylem-fibre; or (4) a vertical file of xylem-parenchyma cells. In the case of the phloem, a mother-cell divided by a number of horizontal walls. A mother-cell of the phloem may give rise to (1) a segment of a sieve-tube with its companion cell or cells; (2) a phloem-fibre; (3) a single phloem-parenchyma (cambiform) cell, or a vertical file of phloem parenchyma cells. This does not give rise to xylem and phloem elements, but cuts off cells on both sides that elongate radially and divide by horizontal walls until a given initial cell of the cambium has once begun to produce cells of this sort it continues the process, so that a radiate plate of parenchyma cells is formed stretching in one plane through the xylem and phloem. Such a cell-plate is called a medullary ray. It is essentially a living tissue, and serves to place all the living cells of the secondary vascular tissues in communication. It conducts plastic substances inward from the cortex, and its cells are frequently full of starch, which they store in winter. They are also capable of conducting for the conduction of oxygen to, and carbon dioxide from, the living cells in the interior of the wood, which would otherwise be cut off from the means of respiration. The xylem and phloem parenchyma consist of living cells, remaining at a compact mass of musculature and intercellular parenchyma cells, which sometimes replace them altogether. The parenchyma is often arranged in tangential bands between the layers of sieve-tubes and tracheal elements. The xylem parenchyma is often found in strands associated with the tracheal elements. These strands are not isolated, but form a connected network through the wood. The xylem parenchyma cells are connected, as are the members of a single tracheal strand, by tracheal or vascular strands, or pits—i.e., pits with a border on the tracheal element side, and simple on the parenchyma cell side. The fibres are frequently found in tangential bands between similar bands of tracheae or sieve-tubes. The fibres are frequently solid, forming a cylinder in the diameter, with an inner cambial layer, the parenchyma, which forms a periderm. The cambium is a cylinder next the cambium, remains alive and carries on the active functions of the xylem, particularly the conduction of water. The heart-wood ceases to be of any use to the tree except as a support, but owing to its dryness and resistance of much use in industrial purposes. The hard heart-wood is deposited in the heart-wood, and the secondary tissues of various woods, such as sycamore, oak, and maple, are confined to the heart-wood. In some cases, the heart-wood, which remains fundamentally hard, remains soft and easily cut. This is the case in those cases, as is common in the case of the oak, in which the heart-wood is formed at very different epochs in the life of a tree, according to the species (e.g. in the case of the oak, forty years in the ash, &c. in the case of the pine, two years).
In many annual plants no cambium is formed at all, and the same is true of most perennial Pteridophytes and Monocotyledons.

When the vascular tissue of such plants is arranged in separate bundles these are said to be simple. The bundles of plants which form cambium are, on the contrary, called open. In stems with open bundles the formation of cambium and secondary tissue may be confused with the fascicular cambium. That case either very lightly divided secondary tissue is formed, as in the gourds, some Runuculaeae, &c., or a considerable amount may be produced (clematis, barberry, ivy). In the latter event the cells of the primary rays are either merely stretched radially, or they divide to keep pace with the growth of the bundles. If this division occurs by means of a localized secondary meristem connecting the cambial layers of adjacent bundles, an interfascicular cambium is formed in addition to the fascicular cambium. The interfascicular cambium may form nothing but parenchymatous tissue, producing merely continuations of the primary rays. Such rays are usually broader and more massive than the secondary rays formed within the wedges of wood opposite the primary bundles, and are distinguished as primary rays from the narrow secondary rays. (fig. 24). This is the typical case in most trees where the primary bundles are closely set together. Where the primary bundles are farther apart, so that the primary rays are wider, the interfascicular cambium may form several fairly broad (principal) secondary rays in continuation of certain radial bands of the primary ray, and between these, weds of secondary xylem and phloem; or, finally, secondary xylem and phloem may be formed by the whole circumference of the cambium, fascicular and interfascicular alike, interrupted only by narrow secondary rays, which have no relation to the primary ones.

In a great many cases, sometimes in isolated genera or species, sometimes characteristic of whole families, so-called anomalous cambial layers are formed in the stem, either as an extension of, or addition to, the original cambial cylinder. These are frequently associated with irregularities in the activity of the original cambium. Irregularity of cambium occurs in various families of woody dicotyledonous plants, mostly among the woody climbers, known as lianes, characteristic of tropical and sub-tropical forests.

In the simplest cases the cambium produces xylem more freely along certain tracts of the circumference than along others, so that the stem bears its original cylindrical form and becomes elliptical or oblong in cross-section. This is to be seen abundantly in those places where the secondary xylem is deficient, so that the stem remains cylindrical in section, the phloem occupying the bays left in the xylem mass. Sometimes in such cases the cambium ceases to be active round these bays and joins across the outside of the bay, where it resumes its normal activity, thus isolating a phloem strand, or, as it is sometimes called, a phloem island, in the midst of the xylem. The significance of these phenomena, which present many minor modifications in different cases, is not fully understood, but one purpose of the formation of phloem promontories and islands seems to be the protection of the sieve-tubes from crushing by the often considerable peripheral pressure that is exercised on the stems of these lianes. Sometimes the original cambial ring is broken into several arcs, each of which is completed into an independent cambium and thus secondary xylem and phloem are formed. The formation of additional cambial cylinders or bands occurs in the most various families of Dicotyledons and in some Gymnosperms. They may arise in the pericycle or endodermis in the cortex of the petiole, in the mesophyll of the secondary xylem or phloem. The activity of the new cambium is often associated with the stoppage of the original one. Sometimes the activity of the new cambium involves the formation of concentric rings or arcs of secondary xylem and phloem. In other cases a more intricate arrangement of secondary tissue masses is produced, quite impossible to interpret unless all stages are observed. The cambial cells may grow along the whole stem breaks up into separate woody strands, often twisted like the strands of a rope, and running into one another at intervals. An ordinary cambium is scarcely ever found in the Monocotyledons, as there is often only a single wood and cambium produced by the primary bundles, and gives rise externally to a little secondary cortex, and internally to a secondary parenchyma in which are developed numerous zones of additional bundles, usually of concentric structure, with phloem surrounded by xylem.

The cambium in the root, which is found generally in those plants which possess a cambium in the stem, always begins in the conjunctive tissue internal to the primary phloems, and in the cambial cylinder of secondary xylem. (fig. 25). In roots, which thicken but slightly, whose cambium usually appears late, and that is formed toward the end, the cambial layer is more copiously formed at the ends of the roots. If the cambium in these vascular tissues is to proceed further, arcs of xylem and phloem are formed in the pericycle external to the primary xylems, and the two sets of cambial arcs join, forming a continuous, wavy line on transverse section, which is opposite the primary cambium. If the cambium of the vascular tissues is to proceed further, arcs of xylem and phloem are formed in the pericycle external to the primary xylems, and the two sets of cambial arcs join, forming a continuous, wavy line on transverse section, which are opposite the primary cambium.

The cambium of the primary root, together with the tissues which it forms, is always directly continuous with that of the primary stele, just in the same way as the tissues of the primary stelae. The so-called anomalous cambiums in roots follow the same lines as those of the stem.

In nearly all plants which produce secondary vascular tissues cambia are formed in cambial cylinders of secondary tissues, arising externally to, but in quite the same fashion as, the cambium, and producing like the latter an external and an internal secondary tissue. This is the phellogen, and internal cambial cylinder of secondary phloem and xylem, termed the periderm. The phellogen derives its name from the fact that its external product is the characteristic tissue known as cork. This consists typically of close-fitting layers of cells with thick, suberized walls, intended to replace the external protective layer of the plant when the latter, incapable as it is of further growth after its original formation, is broken off and cast off by the increase in thickness of the stem through the activity of the cork. It also is formed similarly in the root after the latter has passed through its primary stage as an absorptive organ, and its structure is becoming assimilated to that of the stem. The internal tissue formed by the phellogen is known as phelloderm, and consists usually of ordinary parenchyma. The phellogen may arise, in the first place, in any tissue of the axis external to the actual vascular tissues—i.e., in the epidermis itself (rarely), in any layer of the cortex or phelloderm, or in the cortex itself. In the phelloderm the stem is the external layer of the cortex immediately below the epidermis; in the root, the pericycle. All the tissues external to the cork are cast off by the plant. The extent of development of the phelloderm is dependent upon whether the phellogen has a superficial or a deep-seated origin. In the former case the formation of phelloderm is trivial in amount; in the latter, considerable, since this tissue has to replace the cast-off cortex, as a metabolic and protective layer.

Provision is made for gaseous interchange between the internal tissues and the external air after the formation of cork, by the development of a network of phloem tubes that are spirally arranged and interrupt the continuity of the impermeable layer of ordinary cork-cells. A lenticel is formed by the phellogen at a given spot dividing very actively and giving rise to a loose tissue of phloem and xylem strands, which wind and twist around the trunk, and the air can pass to the tissues below (fig. 25). A lenticel appears to the naked eye as a rounded or elongated scar, often forming a distinct prominence on the surface of the organ. The lenticels of the stem are usually formed beneath stomata, whose function they take up after the formation of cork, but the lenticels of the root are formed externally to the cortex to which they are in direct connection.

Fig. 24.—Section of three-year-old stem of Lime. (X 20.)

A, periderm; B, cortex; C, phloem with alternating strands of fibres, sieve-tubes and parenchyma; D, L., principal ray; E, R., subordinate ray; O, cambium.

In plants a cambial cylinder is formed by the cambial layer, or cambium, which consists of primary meristematic tissue that gives rise to the secondary tissues of xylem and phloem.
PLANTS

stomata have been ruptured and cast off with the rest of the epidermis. Both cork and phelloderm may be differentiated in various ways. The former often attains the level of the secondary phloem, and are formed in the parenchyma of the latter, keeping pace in their inward march with the formation of fresh secondary phloem by the cambium. The complex system of dead and dying tissues cut off by these successive periderms, together with the latter themselves—in fact, everything outside the innermost phellogen—is what is often known botanically as the bark of the tree. Rhytidome is, however, a preferable term, as the word bark has long been established in popular usage to mean all the tissues that can easily be peeled off—i.e., everything down to the wood of the tree. The rough surface of the bark of many trees is due to the successive phellodermes not arising in regular concentric zones, but forming in arcs which join the innermost phellogen of the stem. Special "wound-cork" is also often formed round accidental injuries so as to prevent the rotting of the tissues by the soaking in of rain and the entrance of fungal spores and bacteria. A peculiar modification of periderm is formed by the phellogen in the submerged organs (roots or stems) of many aquatic or marsh-loving plants. This may take various forms and may cover the whole of the organ or be localized in special regions; but its cells are always living and are filled by very large intercellular spaces containing air. This tissue is called parenchyma, and no doubt its function is to facilitate the respiration of the organs on which it is formed and to which the access of oxygen is difficult. In other cases, a similar formation of the peridermium may occur for the same purpose in special patches, called pneumatodes, on the roots of certain trees living in marshy places, which rise above the soil in order to obtain air.

History and Bibliography.—The study of plant anatomy was begun in the middle of the seventeenth century as a direct result of the construction of microscopes, with which a clear view of the structure of plant tissues could be obtained. The Englishman Grew and the Italian Malpighi almost simultaneously published illustrated works on the subject, in which they described, for the most part very accurately, what they saw with the new instruments. The subject was practically dormant for nearly a century and a half, largely owing to the dominance of classificatory botany under the influence of Linnaeus. It was revived by several German workers, prominent among whom were Treviranus and Link, and later Moldenhawer, as well as by the Frenchmen Mirbel, at the beginning of the 19th century. The new work largely centred round a discussion of the nature and origin of vessels, conspicuous features in young plant tissues which thus acquired an importance in the contemporary literature out of proportion to their real significance in the construction of the vascular plant. The whole of the writings of this time are marked by a preoccupation with the functions of the different tissues, in itself an excellent standpoint for investigation, but frequently leading in the case of these early investigators to one-sided and distorted views of the facts of structure. The pioneer of modern plant anatomy was Hugo von Mohl (fl. 1830), who carefully investigated and described the facts of anatomical structure without attempting to fit them into preconceived views of their meaning. He produced a solid body of accurately described facts which has formed the secure groundwork of subsequent advance. From Mohl down to the eighth decade of the century the study of plant anatomy was entirely in the hands of a group of German investigators, prominent among whom were several of the most eminent founders of modern scientific botany—such, for instance, as Nigeli, Sanio and De Bary. To the first we owe the secure foundation of our knowledge of the structure and course of the vascular strands of the higher plants ("uber den Bau und die Anordnung der Gefässbündel bei den Stamm und Wurzel der Phanerogamen," Studien zur wissenschaftlichen Botanik, ii, Leipzig, 1859); to the second the establishment of the sound morphological doctrine of the central cylinder of the axis as the starting-point for the consideration of the general arrangement of the tissues, and the first clear distinction between primary and secondary tissues (Botanische Zeitung, 1851 and 1863); to the last the putting together of the facts of plant anatomy known up to the middle of the eighth decade of the century in that great encyclopedia of plant anatomy, the "Vergleichende Anatomie der Vegetationsorgane und Farnen (Stuttgart, 1876; Eng. trans., Comparative Anatomy of the Vegetative Organs of the Phanerogams and Ferns, Oxford, 1882). In 1870-1871 Van Tieghem published his great work, "Sur la Racine," Ann. sci. nat. bot. (Paris). This was not only in itself an important contribution to plant anatomy, but served as the starting-point of a series of researches by Van Tieghem and his pupils, which has considerably advanced our knowledge of the details of histology, and also culminated in the foundation of the doctrine of the stelae (Van Tieghem and Douliot, "Sur la polystylie," Ann. sci. nat. bot., ii. x., 1880-1881). This has had a most important effect on the development in recent years of morphological anatomy.

In the progress of the last three decades, since the publication of De Bary's great work, five or six main lines of advance can be distinguished. First, the knowledge of the details of histology has of course advanced greatly in the direction through the ceaseless activity of very numerous, mainly German, workers, though no fundamentally new types of tissue have been discovered. Secondly, the histology of fossil plants, particularly woody plants and stump remains, has been placed on a sound basis, assimilated with general histological doctrine, and has considerably enlarged our conceptions of plant anatomy as a whole, though again without revealing any entirely new types of structure. This branch of the subject, founded by Corda, Göppert, Stenzel and others in Germany, was enormously advanced by Williamson's work on the Coal Measures plants, recorded in the magnificent series of memoirs, "Researches on the Organization of Fossil Plants of the Coal Measures" (Phil. Trans. Roy. Soc., vols. i.-x., 1871-1893). The work of solms Laubach in Germany, Renault and Bertrand in France, and of the earlier years of Zeller in France, and Scott, Seward and others in England, has advanced our knowledge of the anatomy of fossil plants in an important degree. While convincing us that the plants of past ages in the earth's history were exposed to very similar conditions of life, and made very much the same adaptive responses as their modern representatives, one of the main results of this line of work has been to reveal important data enabling us to fill various gaps in our morphological knowledge and to obtain a more complete picture of the evolution of tissues in the vascular plants. One of the most striking incidents in the progress has been the recognition within the last few years of the existence of an extinct group of plants lying on the borderland between Filicales and Gymnosperms, now known as the Cycadofilices, a group in which, curiously enough, the reproductive organs remained undiscovered for some time after the anatomy of the vegetative organs was sufficiently well known to afford clear evidence of their true affinities. Thirdly, we have to record very considerable
progress in our knowledge of distinctively morphological anatomy, i.e. the study of tissues from the standpoint of evolution. The Russian plant-anatomist, Russow, may be said to have founded the consideration of plant tissues from the point of view of descent (Vergleichende Untersuchungen über die Leitbündelkryptogamen, St Petersburg, 1872; and Betrachtungen über Leitbündel und Grundgewebe, Dorpat, 1872). He was ably followed by Strasburger (Über den Bau und die Verrichtungen der Leitungsbahnen in den Pflanzen, Jena, 1891), Haberlandt and others. The explicit adoption of this point of view has had the effect of clearing up and rendering definite the older morphological doctrines, which for the most part had no fixed criterion by which they could be tested.

Since about 1893 this branch has been most actively pursued in England, where the work of Boodle and of Gwynne-Vaughan (especially on Ferns) has been the most important, leading to a coherent theory of the evolution of the vascular system in these plants (Tansey, Evolution of the Filicinaceae Vascular System, Cambridge, 1908); and in America, where Jeffreys has published important papers on the morphology of the vascular tissues of the various groups of Pteridophytes and Phanerogams and has sought to express his conclusions in a general morphological theory with appropriate terminology. As a result of this activity Van Tieghem's so-called "Stellar theory" has been revised and modified in the light of more extended and detailed anatomical and developmental knowledge. Schoute's Die Stell-Theorie (Grüningen, 1902), gives an important critical account of this subject.

Fourthly, attention must be called to the great development of what is called "Systematic Anatomy," i.e. the study of the anatomical features characteristic of the smaller groups of flowering plants, i.e. the orders, families, genera and species. Radlikоff (1883) was the first to call attention to the great importance of this method in systematic botany, as providing fresh characters on which to base a natural classification. Solereder's great work, Systematische Anatomie der Dicotylen (Stuttgart, 1898-1908; Eng. trans., Systematic Anatomy of Dicots, Oxford, 1908), brings together so many of the facts as are at present known in an orderly arrangement. Theoretically this branch of the subject should connect with and form the completion of "morphological anatomy," but the field has not yet been sufficiently explored to allow of the necessary synthesis. The true relation of "systematic" to "ecological" anatomy (see below) also awaits proper elucidation.

Fifthly, we have to record the foundation of the modern study of "physiological anatomy" (i.e. the study of the specific functions of the various tissues) by Schwendener (Das mechanische Prinzip im Pflanzenleben, 1874, and other works), followed by numerous pupils and others, among whom Haberlandt (Physiologische Pflanzen-Anatomie, Leipzig, 1st ed., 1884, 4th ed., 1909, and other works) is pre-eminent. The pursuit of this study has not only thrown valuable light on the economy of the plant as a whole, but forms an indispensable condition of the advance of morphological anatomy. A great deal of work still remains to be done in this department, which at the present time affords one of the most promising fields of anatomical investigation.

Finally we may mention "ecological anatomy," i.e. the study of anatomical features directly related to the habitat. A very considerable body of knowledge relating to this subject already exists, but further work on experimental lines is urgently required to enable us to understand the actual economy of plants growing under different conditions of life and the true relation of the hereditary anatomical characters which form the subject matter of "systematic anatomy" to those which vary according to the conditions in which the individual plant is placed. On these lines the future of anatomical study presents almost inexhaustible possibilities. (A. G. T.)

**Physiology of Plants**

The so-called vegetable physiology of a generation ago was in arrear of animal, and particularly of human, physiology, the study of the latter being followed by many more observers, and from its relative degree of advancement being the more capable of rapid development. It was fully recognized by its followers that the dominating influence in the structure and working of the body was the protoplasm, and the division of labour which it exhibited, with the accompanying or resulting differentiation into various tissues, was the special subject of investigation. Many who followed the study of vegetable structure did not at that time give an equal prominence to this view. The early histological researches of botanists led them to the recognition of the vegetable cell, and the leading writers in the middle of the 19th century pointed out the probable identity of Von Mohl's "protoplasm" with the "sarcode" of zoologists. They laid great stress on the nitrogenous nature of protoplasm, and noted that it preceded the formation of the cell-membrane. But by the ordinary student of thirty years later their work was to some extent overlooked, and the cell-wall assumed a prominence to which it was not entitled. The study of the differentiation of protoplasm was at that time seldom undertaken, and no particular attention was paid either to fixing it, to enable staining methods to be accurately applied to it, or to studying the action of chemical reagents upon it. It is only comparatively recently that the histological investigation used by animal physiologists has been carefully and systematically applied to the study of the vegetable organisms. They have, however, been attended with wonderful results, and have revolutionized the whole study of vegetable structure. They have emphasized the statements of Von Mohl, Cohn, and other writers alluded to, that the protoplasm is here also the dominant factor of the body, and that all the peculiarities of the cell-wall can only be interpreted in the light of the needs of the living substance.

The Nature of the Organization of the Plant, and the Relations of the Cell-Membrane and the Protoplasm.—This view of the structure of the plant has been reached by many methods of investigation lead us to a greatly modified conception of its organization, and afford more completely an explanation of the peculiarities of form found in the vegetable kingdom.

The study of simple organisms, many of which consist of nothing but a little mass of protoplasm, exhibiting a very rudimentary degree of differentiation, so far as our methods enable us to determine any at all, shows that the duties of existence can be discharged in the absence of any cell-wall. Those organisms which possess the latter are a little higher in the scale of life than those which remain unclothed by it, but a comparison of the behaviour of the two quickly enables us to say that the membrane is of but secondary importance, and that it is not of itself the organ which actually enables it to be a mature tissue specific with an electric covering for the living substance. Its physical properties, permeability by water, extensibility and elasticity, receive their interpretation in the needs of the latter. We come, accordingly, to regard it as practically an exoskeleton, and its functions as distinctly subordinate to those of the protoplasm which it clothes. If we pass a little higher up the scale of life we meet with forms consisting of two or more cells, each of which contains a similar minute mass of living substance. A study of them shows that each is practically independent of the others; in fact, the connexion between them is so slight that they can separate and each become free without the slightest disadvantage to another. So long as they are connected together mechanically they have appeared the power of influencing one another in various ways, and of passing liquid or gaseous materials from one to another. The joined organism is, in fact, a colony or association of the protoplasmic units, though each unit retains its independence. When we pass, again, from these to examine more bulky, and consequently more complex, plants, we find that the differences which can be observed between them and the simple lowly forms are capable of being referred to the increased number of the protoplasmic units and the consequent enlarged bulk of the mass or colony. Every plant is thus found to be composed of a number of these protoplasmic units, or, as they may preferably be termed,
protoplasts, all of which are at first exactly alike in appearance and in properties. This is evident in the case, of such plants as have a body consisting of filaments or plates of cells, and is little less conspicuous in those whose mass is but small, though the cells are evidently capable of computation in three dimensions. In such cases it does not appear to be the same with the bulkier plants, such as the ordinary tree, for instance; but a study of their earlier development indicates that they do not at the outset differ in any way from the simple undifferentiated forms. Each commences its existence as a simple naked protoplast, in the embryo-sac or the archegonium, as the case may be. After the furious fusion with another similar protoplast, which constitutes what we call fertilization, the next stage in complexity already noted may be observed, the protoplasm becoming clothed by a cell-membrane. Very soon the single cell gives rise to a chain of cells, and this in turn to a cell mass, the individual units of which are at first quite uniform. With increase of number, however, and consequently enlargement of bulk in the colony, differentiation becomes compulsory. The requirements of the several protoplasts must be met by supplies from without, and, as many of them are deep seated, varieties of need arise, so that various members of the colony are set apart for special duties, masses of them being devoted to the discharge of one function, others to that of another, and so on. Such limitations of the powers and properties of the individuals have for their object the well-being of the community of which those individuals are constituents.

**Physiological and Morphological Differentiation.**—The first indication of this differentiation in the vegetative body of the plant can be seen not only in the terrestrial green plants which have been particularly referred to, but also in the bulkier seaweeds. It is an extension of the first differentiation which was observable in the simple protoplasts first discussed, the formation, that is, of a protective covering. *Fucus* and its allies, which form conspicuous members of the larger Algae, have their external cells much smaller, more closely put together, and generally much denser than the rest of their tissue. In the lowly as well as the higher green plants we have evidence of specialization of the external protoplasts for the same purpose, which takes various shapes and shows different degrees of completeness, culminating in the elaborate barks which clothe our forest trees.

The second prominent differentiation which presents itself takes the form of a provision to supply the living substance with water. This is a primal necessity of the protoplast, and every cell gives evidence of its need by adopting one of the various ways in which such need is supplied. What little differentiation can be found to exist in the protoplasm of the simple unicellular organism shows the importance of an adequate water-supply, and indeed, the dependence of life upon it. The naked cells which have been alluded to live in water, and call therefore for no differentiation in connexion with this necessity; but those which are surrounded by a cell-wall always develop within themselves a vacuole or cavity which occupies the greater part of their interior, and the hydrostatic pressure of whose contents keeps the protoplasm in contact with the membrane, setting up a condition of turgidity.

The need for a constant supply of water is partly based upon the constitution of protoplasm, so far as we know it. The apparently structureless substance is saturated with it; and if once a cell is completely dried, even at a low temperature, in the enormous majority of cases its life is gone and the restoration of water fails to enable it to recover. Besides this intimate relationship, however, we can point to other features of the necessity for a constantly renewed water supply. The protoplasm, deprived of its food in solution in water; the various waste products which are incident to its life are excreted into it, and so removed from the sphere of its activity. The raw materials from which the food is constructed are absorbed from the exterior in solution in water, and the latter is the medium through which the gaseous constituents necessary for life reach the protoplasm. Moreover, growth is essentially dependent upon water-supply. There is little wonder, then, that in a colony of protoplasts such as constitute a large plant a considerable degree of differentiation is evident, bearing upon the question of water supply. Certain cells of the exterior are set apart for absorption of water from the soil, this being the source from which supplies are derived. Others are devoted to the development of various parts of the plant, and to the growth of it to the protoplasts situated in the interior and at the extremities of the plant, a conducting system of considerable complexity being the result.

Other collections of cells are in many cases set apart for giving rigidity and strength to the mass of the plant. It is evident that as the latter increases in bulk, more and more attention must be paid to the dangers of uprooting by winds and storms. Various mechanisms have been adopted in different cases, some connected with the subterranean and others with the sub-aerial portions of the plant. Another kind of differentiation in such a cell-mass as we are dealing with is the setting apart of particular groups of cells for various metabolic purposes. We have the formation of numerous mechanisms which have arisen in connexion with the question of food supply, which may not only involve particular cells, but also lead to differentiation in the protoplasm of those cells, as in the development of the chloroplasts of the leaves and other green parts.

The inter-relations of the members of a large colony of protoplasts such as constitute a tree, demand much adjustment. Relations with the exterior are continually changing, and the needs of different regions of the interior are continually varying, from time to time. Two features which are essentially protoplasmic assume a great importance when we consider these relations. They are the power of receiving impressions or stimuli from the exterior, and of communicating with each other, with the view of co-ordinating a suitable response. We have nothing structural which corresponds to the former of these. In this matter, differentiation has proceeded only differently in animals and plants respectively, no nerves or sense organs being structurally recognizable. Communication between the various protoplasts of the colony is, however, carried on by means of fine protoplasmic threads, which are continuous through the cell-walls.

All the peculiarities of structure which we encounter consequently support the view with which we started, that the protoplasm of the plant is the dominant factor in vegetable structure, and that there need be but one subject of physiology, which must embrace the behaviour of protoplasm wherever found. There can be no doubt that there is no fundamental difference between the living substance of animals and plants, for many forms exist which cannot be referred with certainty to either kingdom. Free-swimming organisms without cell-membranes exist in both, and from them series of forms can be traced in both directions. Cellulose, the material of which vegetable cell-walls are almost universally composed, at any rate in their early condition, is known to occur, though only seldom, among animal organisms. Such forms as Volvox and the group of the *Meynomyceces* have been continually referred to both kingdoms, and their true systematic position is still a subject of controversy. All physiology, consequently, must be based upon the identity of the protoplasm of all living beings.

This method of study has to a large extent modified our ideas of the relative importance of the parts of such an organism as a large tree. The interest with which we regard the latter no longer turns upon the details of the structure of its trunk, limbs and roots, to which the living substance of the more superficial parts was subordinated. Instead of regarding these as only ministering to the construction of the bulky portions, the living substance may take them as the essential portion of the tree, and all the other features are important mainly as ministering to their individual well-being and to their multiplication. The latter feature is the growth of the tree, the well-being of the protoplasts is its life and health. The interest passes from the bulky dense interior, with the elaborate features of its cell-walls, to the superficial parts, where its life is in evidence. We see herein the reason for the great subdivision of the body, with its
finely cut twigs and their ultimate expansions, the leaves, and we recognize that this subdivision is only an expression of the need to place the living substance in direct relationship with the environment. The formation and gradually increasing thickness of its bark are explained by the continually increasing need of adequate protection to the living cortex, under the strain of the increasing frame by which the enormous multiplication of its living protoplasts demands, and the development of which leads to continual rupture of the exterior. The increasing development of the wood as the tree grows older is largely due to the demands for the conduction of water and mineral matters dissolved in it, which are made by the increased number of leaves which from year to year it bears, and which must each be put into communication with the central mass by the formation of new vascular bundles. Similar considerations apply to the peculiar features of the root-system. All these points of structure can only be correctly interpreted after a consideration of the needs of the individual protoplasts, and of the large colony of which they are members.

**Gaseous Interchanges and their Mechanism.**—Another feature of the construction of the plant has in recent years come into greater prominence than was formerly the case. The organism is largely dependent for its vital processes upon gaseous interchanges. It must receive a large constituent of what ultimately becomes its food from the air which surrounds it, and it must also take in from the same source the oxygen of its respiratory processes. On the other hand, the aerial environment presents considerable danger to the young and tender parts, where the protoplasts are most exposed to extremes of heat, cold, wet, &c. These must in some way be harmonized. No doubt the primary object of the cell-wall of even the humblest protoplast is protection, and this too is the meaning of the coarser tegumentary structures of a bulkier plant. These vary considerably in completeness with its age; in its younger parts the outer cells wall undergoes the change known as cuticularisation, the material being changed both in chemical composition and in physical properties. The corky layers which take so prominent a share in the formation of the bark are similarly modified and subserv the same purpose. But these protective layers are in the main impermeable by gases and by either liquid or vapour, and prevent the access of either to the protoplasts which need them. Investigations carried out by Blackman, and by Brown and Escombe, have shown clearly that the view put forward by Boussingault, that such absorption of gases takes place through the cuticular covering of the younger parts of the plant, is erroneous and can no longer be supported. The difficulty is solved by the provision of a complete system of minute intercellular spaces which form a continuous series of delicate canals between the cells, extending throughout the whole substance of the plant. Every protoplast, except in the very young regions, has part of its surface abutting on these, so that its wall is accessible to the gases necessary for its vital processes. There is no need for cuticularization here, as the external dangerous influences do not reach the interior, and the processes of absorption which Boussingault attributed to the external cuticularized cells can take place freely through the delicate cell-walls of the interior, saturated as these are with water. This system of channels is in communication with the outer atmosphere through numerous small apertures, known as stomata, which are abundant upon the leaves and young twigs, and gaseous interchange between the plant and the air is by their assistance rendered constant and safe. This system of intercellular spaces, extending throughout the plant, constitutes a reservoir, charged with an atmosphere which differs somewhat in its composition from the external air, its gaseous constituents varying from time to time and from place to place, in consequence of the interchanges between itself and the protoplasts. It constitutes practically the exterior environment of the protoplasts, though it is ramifying through the interior of the plant.

The importance of this provision in the case of aquatic vascular plants of sturdy bulk is even greater than in that of terrestrial organisms, as their environment offers considerable obstacles to the renewal of the air in their interior. They are without stomata on their submerged portions, and the entry of gases can only take place by diffusion from the water through their external cells, which are not cuticularized. Those which are only partially submerged bear stomata on their exposed portions, so that their environment approximates towards that of a terrestrial plant, but the completion of which is much less easy and complete, so that they need a much larger reservoir of air in their interior. This is secured by the development of much larger intercellular spaces, amounting to lacunae or passages of very considerable size, which are found ramifying in different ways in their interior.

**Transpiration.**—In the case of terrestrial plants, the continual renewal of the water contained in the vacuoles of the protoplasts demands a copious and continuous evaporation. This serves a double purpose, bringing up from the soil continually a supply of the soluble mineral matters necessary for their metabolic processes, which only enter the plant in solutions of extreme dilution, and at the same time keeping the plant cool by the process of evaporation. The latter function has been found to be of extreme importance in the case of plants exposed to the direct access of the sun’s rays, the heat of which would rapidly cause the death of the protoplasts were it not employed in the evaporation of the water. Brown and Escombe have shown that the amount of solar energy taken up by a green leaf may often be fifty times as much as it can utilize in the constructive processes of which it is the seat. If the heat were allowed to accumulate in the leaf unchecked, they have computed that its temperature would rise during bright sunshine at the rate of more than 12° C. per minute, with of course very rapid fatal results. What is not used in the constructive processes is employed in the evaporation of the water, the leaf being thus kept cool. Whether the leaf is brightly or only moderately illuminated, the same relative proportions of the total energy absorbed are devoted to the purposes of composition and construction respectively. This large evaporation, which constitutes the so-called transpiration of plants, takes place not into the external air but into this same intercellular space system, being possible only through the delicate cell-walls upon which it abuts, as the external coating, whether bark, cork or cuticle, is impermeable by watery vapour. The latter ultimately reaches the external air by diffusion through the trunk. The transpirations vary in proportion as the amount of water in the epidermal cells becomes greater or less.

**Mechanism and Function of Stomata.**—It is not quite exact to speak of either the gaseous interchanges or the transpiration as taking place through the stomata. The entry of gases into, and exit from, the cells, as well as the actual exhalation of watery vapour from the latter, take place in the intercellular space system of which the stomata are the outlets. The opening and closing of the stomata is the result of variation in the turgidity of their guard cells, which is immediately affected by the condition of turgidity of the cells of the epidermis contiguous to them. The amount of watery vapour in the air passing through a stoma has no effect upon it, as the surfaces of the guard cells abutting on the air chamber are strongly cuticularized, and therefore impermeable. The only way in which their turgidity is modified is by the entry of water into them from the contiguous cells of the general epidermis and its subsequent withdrawal through the same channel. This opening and closing of the stomata must be looked upon as having a direct bearing only on the emission of watery vapour. There is a distinct advantage in the regulation of this escape, and the mechanism is directly connected with the greater or smaller quantity of water in the exterior cells of the epidermis. This water of varying amount varying the area of the apertures by which gases enter the internal reservoirs is not advantageous to the gaseous interchanges—indeed it may be directly the reverse. It may lead to an incipient asphyxiation, as the supply of oxygen may be greatly interfered with and the escape of carbon dioxide may be almost stopped. It may at other times lead to great difficulties in the supply of the gaseous constituents which are used in the
manufacture of food. The importance of transpiration, is, however, so great, that these risks must be run.

The Ascend of Water in Trees.—The supply of water to the peripheral protoplasts of a tree is consequently of the first importance. The means by which such a supply is ensured are by no means clearly understood, but most botanists incline to the view that it is drawn up from the roots, by a pressure action similar to that exerted by a pump. The natural source of the water is in all cases the soil, and few plants normally obtain any from elsewhere. The water of the soil, which in well-drained soil is met with in the form of delicate films surrounding the particles of solid matter, is absorbed into the plant by the delicate hairs borne by the young roots, the entry being effected by a process of modified osmosis. Multitudes of such hairs on the branches of the roots cause the entry of great quantities of water, which by a subsequent osmotic action accumulates in the cortex of the roots. The great turgidity of the cortex so caused exerts a considerable hydrostatic pressure on the stele of the root, the vessels of the wood of which are sometimes filled with water, but at other times contain air, and this often under a pressure less than the ordinary atmospheric pressure. This pressure of the turgid cortex on the central stele is known as root pressure, and is of very considerable amount. This pressure leads to the filling of the vessels of the wood of both root and stem in the early part of the year, before the leaves have expanded, and gives rise to the exudation of fluid known as bleeding when young stems are cut in early spring.

Root pressure is one of the forces co-operating in the forcing of the water upwards. The evaporation which is associated with transpiration is no doubt another, but by themselves they are insufficient to explain the process of lifting water to the tops of tall trees. There is at present also a want of agreement among botanists as to the path which the water takes in the structural elements of the tree, two views being held. The other is that the water travels in the woody cell-walls of the vascular bundles, mainly under the action of the forces of root pressure and transpiration, and that the cavities of the vessels contain only air. The other is that the vessels are not empty, but that the water travels in their cavities, which contain columns of water in the course of which are large bubbles of air. On this view the water flows upwards under the influence of variations of pressure and tension in the vessels. These forces however fail to furnish a complete explanation of the ascent of the current, and others have been thought to supplement them, which have more or less weight. Westermaier and Godlewski put forward the view that the living cells of the medullary rays of the wood, by a species of osmosis, act as a kind of pumping apparatus, by the aid of which the water is lifted to the top of the tree, a series of pumping-stations being formed. Though this at first met with some acceptance, Strasburger showed that the action goes on in great lengths of stem the cells of which have been killed by poison or by the action of heat. More recently, Dixon and Joly in Dublin and Askenasy in Germany have suggested the action of another force. They have shown that columns of water of very small diameter are sufficient to resist the tension strain that they can be lifted bodily, instead of flowing along the channel. They suggest that the forces causing the movement are complex, and draw particular attention to the pull upwards in consequence of disturbances in the leaves. In these we have (1) the evaporation from the stomata into the intercellular spaces; (2) the imbibition by the cell-wall of water from the vacuole; (3) osmotic action, consequent upon the subsequent increased concentration of the cell sap, drawing water from the wood cells or vessels which abut upon the leaf parenchyma. They do not, of course, deny the co-operation of the other forces which have been suggested, except so far as these are independent, but they claim them to be supplementary only, and that the principal force is the phloem apparatus of the vegetable kingdom. A consideration of these facts emphasizes still more fully the view with which we set out, that all living substance is fundamentally the same, though differentiated both anatomically and physiologically in many directions and in different degrees. All is nourished alike on materials originally prepared by a mechanism attached to the higher vegetable system, and capable therefore of being considered from its own special means of nutrition, if by the latter word we understand the appropriation by the protoplasm of the materials so constructed.

The phloem apparatus of plants demands a certain description. It consists essentially of a number of minute corpuscles or plastids, the protoplasmic substance of which is impregnated with a green colouring matter. These bodies, known technically as chloroplasts, are found embedded in the protoplasm of the cells of the mesophyll of foliage leaves, of certain of the cells of some of the leaves of the flower, and of the cortex of the young twigs and petioles. Usually
is the nature of the first formed sugar certain; the general opinion has been that it is a simple hexose such as glucose or fructose, or both. In recent years, however, Dr. H. von Euler has suggested, thinking that cane-sugar, C_{12}H_{22}O_{11}, is the first carbohydrate synthesized, and that the hexoses found in the plant result from the decomposition of this carbohydrate. The view is not consistent with the story of the different carbohydrates which will distill in the plant—their relations, and their several functions—requires renewed investigation.

The first visible carbohydrate formed, which one appears so rapidly, is chlorophyll, and it is characteristic of the process of manufacturing carbohydrates from the carbon dioxide which the air contains, and which is absorbed from it after it has entered the intercellular passages and has so reached the cells containing the plastids. This action of the leaves is not only for the benefit of the plant, preferring moderate sunlight. The reason for the distribution of the chloroplasts described above is consequently seen. The relation of the chlorophyll to light has been studied by many observers. If a solution of chlorophyll is placed in the beam of light which is then allowed to fall on a prism, the resulting spectrum will be found to be modified. Instead of presenting an appearance of a continuous band in which all the colours are represented, it is interrupted by seven vertical dark spaces. The explanation which absence of the solution of chlorophyll would have occupied those spaces have no power to pass through it, or in other words chlorophyll absorbs those particular rays of light which are missing.

The absorption of these rays implies that the pigment absorbs radiant energy from the sun, and gives us some explanation of its power of constructing the carbohydrates which has been mentioned and which so many of the apparatus, working with this light, is all completely understood present, nor can we say exactly what is the part played by the pigment and what is the role of the protoplasm of the plastid. It is not certain either whether the action of the chlorophyll on the plastids is in the formation of the carbohydrates or whether it is concerned, and if so how far, with the construction of protoids also.

As the action of the chlorophyll apparatus is directly dependent upon the presence of light and when the plant is subjected to a suitable temperature, photosynthesis commences provided that the plant has access to air containing its normal amount of carbon dioxide, about 3 parts, or rather less, in 10,000. The essential requirement of inter-action with light is also, as we have seen, is always present in the cell. In addition, certain inorganic salts, particularly certain compounds of potassium, are apparently necessary, but they seem to take no part in the chemical changes which take place. Other elements, such as iron, have also been suggested that the course of events is the following: the carbon dioxide is decomposed into carbon monoxide and oxygen, while water is simultaneously split up into hydrogen and oxygen; the hydrogen and carbon monoxide combine to form formic acid, and the oxygen is exhaled. This explanation is unsatisfactory from many points of view, but till quite recently no alternative has been advanced. It is evident that a certain amount of oxygen is produced, indeed there are strong reasons for disbelieving in its occurrence. The formation of formic acid has till recently not been satisfactorily proved, though it has been obtained from certain leaves, and certain Algae. The formation of carbohydrates from monoxide, formic acid, and oxygen contained in the tissue of the plant, is an example of what is termed assimilation. But it is certain that it can only be present in a cell in very small amount at any time, an excess of the product solution acts as a poison to protoplasm. If formed, as it probably is, it is immediately changed into some more complex combination, and so rendered incapable of exerting its poisonous action.

Baeyer's hypothesis was entertained by botanists partly because it explained the gaseous interchanges accompanying photosynthesis. These show that a definite intake of carbon dioxide is always accompanied, and in the production of an oxygen output of a certain amount. Recent investigations have confirmed Baeyer's view of the formation of formic acid, but a different explanation has been recently advanced. The first chemical change suggested is an interaction between carbon dioxide and water, not through chlorophyll, which leads to the simultaneous formation of formaldehyde and hydrogen peroxide. The formaldehyde at once undergoes a process of condensation or polymerization by the proto-plasmic fluids, until the latter is decomposed into water and free oxygen by another agency in the cell, of the nature of one of the enzymes of which we shall speak later.

Polymerization of the aldehyde was also a feature of Baeyer's hypothesis, so that this view does not very materially differ from those he advanced. More emphasis is, however, now laid on the action of the enzymes in the polymerization, while the initial stages are still not definitely explained.

The steps which lead from the appearance of formaldehyde to that of the first well-defined carbohydrate are again matters of speculation. The actual set of steps in the process is probably simpler than sugar has so far been detected. Nor
PHYSIOLOGY

PLANTS

nitrogen." As this is not the incorporation of either into the living substance, but is only its manufacture into the complex substances which we find in the plant, it seems preferable to limit the term "assimilation" to the processes by which foods are actually taken into the plant processes.

Symbiosis.—Though green plants thus possess a very complete mechanism for the manufacture of their different foodstuffs, it is not always exercised to the fullest extent. Many of them are known to acquire, directly or indirectly, their nitrogenous materials not by taking up the food they need in a fully prepared condition from their environment. It may be that they procure it from decomposing organic matter, or soil, or they may get it by absorption from other plants to which they attach themselves, or they may in rare cases get it by preying upon insect life. The power of green plants, not even specialized in any of these directions, to absorb certain carbohydrates, proteins, and lipoids, has been experimentally proved by Acton in 1889. Similar observations have been made in the case of various compounds of nitrogen, though these have not been so complex as the proteids. It was formerly the custom to regard all substances, for they are attracted to the neighbourhood of the plant with the tissues of other plants and absorbed the contents of the latter. The most conspicuous case, perhaps, of all these is the mistletoe, which nourishes luxuriantly upon the apple, the poplar and other trees. Bonnier has drawn attention to the fact that mistletoe in its turn, remaining green in the winter, contributes food material to its host when the latter has lost its leaves. The relation is not always existing, but it has been found, by one end or another supplying the necessities of the other. Such a relationship is known as symbiosis, and the large majority of the cases of so-called parasitism among green plants can be referred to it. The term was first applied to the same group of cases by those who regard the cases of such plants as the rattle (Rhinanthus), the eye-bright (Euphrasia), and other members of the Natural Orders, Scrophulariaceae and Santalaceae, which effect a union between their roots and the filaments of the fungus, and thus obtain nourishment from the soil, while most plants require it from the plants which they injure. The case of a pronounced case of parasitism, that of Cuscuta, the dodder, which infects particularly clover fields, appears to differ only in degree from this. The plant in whose place underground, while the bulk of both partners in the symbiosis rises into the air, renders the association a little difficult to see, but there is no doubt that the plants in question do afford each other assistance, and that the former are, as a result of the partnership, the more the advantages. The advantages which it can offer to its host, however, is infinitesimal when compared with the injury it does it. Many other cases of symbiosis have been investigated with some success, but only a few are satisfactorily understood. The Phanerogams are concerned. The relations of the Alga and the Fungus, which have formed a close associationhip in the structure known as the Lichen, were established many years ago. Since about 1880 our knowledge of the species which can enter into such relationships has been materially extended, and the fungal constituents of the Lichens are known to include Basidiomycetes as well as Ascomycetes.

Symbiosis.—The most interesting cases, however, in which Fungi form symbiotic relationships with green plants have been discovered in connexion with forest trees. The roots of many of the deciduous trees have in the last 30 years been investigated with a dense feltwork of fungal mycelium, which sometimes forms a mass of considerable size. The plants showing it are not forest trees, but include also some Peridiphytes and some of the prothallia of the Lichens. Lichenes are the first to have shown the nature of the relationship was first recognized by Pfefler in 1877, but few cases were known till recent years. Very complete examination, however, has now been made of many instances, and the name symbiosis has been given to the symbiotic union. Two classes are recognized. In the first, which are called ectotrophic, the fungal filaments form a thick felt or sheath round the root, either completely enclosing it or leaving the apex free. They seldom penetrate the living tissue, but spread so as in a layer between masses of the hyphae of the Fungus. This type of mycorhiza is found among the Poplars, Oaks and Firs trees. The other type is called endotrophic. The fungus filaments take their place in the root-hair, or as it may be seen, from the stem and ramify in the interior. Some make their way through the cells of the outer part of the cortex towards the root-tip, and form a mycelium or hyphae, and others grow to the general thickness of the cells. From this branches pass into the middle region of the cortex and ramify through the interior half of its cells. They often cause a considerable hypertrophy of the tissue. From the outer cortical masses the filaments pass out through the inner walls into the soil. In such cases the roots of the plants are usually found spreading in soils which contain a large amount of humus, or decaying vegetable matter. The organic compounds of the latter are taken up, although, in the case of the Poplar, the part of the root-hair, the tissue ceasing to develop the latter. The food so absorbed passes to the outer cortical mycelium, and from this to the inner hyphae, which appear to be the organs of the interchange of food between the two organisms. In these cases the nuclei of the cells, which they enter, and in which they form agglomerations of interwoven filaments. The protallohi of the Peridiphytes, which form similar symbiotes, show a somewhat different mode of arrangement, the Fungi occupying the external or the lower layers of the thalloid body.

The discovery of the widespread occurrence of this mycorhizal symbiosis must be taken to be one of the most important results of research upon the nutritive processes of the roots during the past decade of the 19th century. Among green plants the symbiotes include Conifers, Orchids, Heaths, Oaks, Poplars and Beeches, while the Fungi and flowers of the Pyrenomycetes, Agarici, Lactarius, Penicillium and most of the other classes. All the known species belong to the Oomycetes, the Pyrenomycetes, the Hymenomycetes or the Gasteromycetes. The habitat of forming mycorhizas is found more frequently in warm climates than cold; indeed, the percentage of the flora exhibiting this peculiarity seems to increase with a certain regularity from the Arctic Circle to the equator.

The family of Nitrogen.—Another, and perhaps an even more important, instance of symbiotic association has come to the front during the same period. It is an alliance between the plants of the Natural Order Leguminosae and certain bacteria, the forms which find a home in the nodules of the roots of the trees. The tree is called a nitrogen-fixing tree. The symbiosis can only be understood by considering the relationship in which plants stand with regard to the free nitrogen of the air. Long known all plants derive their nutritive advantages from the association of the combined nitrogen found in different forms within the plant. After examination, particularly by Boussingault, and later by Lawes and Gilbert and by Pugh, and it was ascertained to be erroneous, the work of the Leguminosae and their partners. The nitrogen of the soil is absorbed by their roots in the form of nitrates of various metals, or compounds of ammonia. Many writers in recent years, among whom may be named especially Heilrigeil and Willfarth, Lawes and Gilbert, and Boreau and Lorrain, have shown that the Leguminosae as a group form conspicuous exceptions to this rule. While they are quite capable of taking up nitrates from the soil where and so long as they grow, they do not grow and thrive in soil which contains no combined nitrogen. It is only by the means of the nitrogen-fixing trees that it is possible for the power of fixing atmospheric nitrogen by the higher plants seems to be confined to this solitary group, though it has been stated by various observers with more or less emphasis that it is shared by others. Frank has claimed to have found oats, buckwheat, spurry, turnips, mustard, potatoes and Norwegian maples exercising it; Noble and others have imputed its possession to Elaeagnus. There is little direct evidence pointing to this extension of the power, and many experimenters directly contradicted the statement.

The power exercised by the Leguminosae is associated with the presence of curious tubercular swellings upon their roots, which are called the nodules, and they are very characteristic of the family. If experimental plants are grown in sterilized soil, these swellings do not appear, and the plant can then use no atmospheric nitrogen. The swellings have been found to be due to a curious hypertrophy of the lower part of the root-hair, owing to the fact that these form a number of minute bacterioid-like organisms of V, X or Y shape. The development of these structures has been studied by many observers, both in England and on the continent of Europe. They appear to be present in large numbers in the soil, and to infect the Leguminous plant by attacking its root-hairs. One of these hairs can be seen to be penetrated at a particular spot, and the entering body then grows along the length of the hair till it reaches the apex of the root. In the appearance of a delicate tube which has granular contents, and is provided with an apex that appears to be open. The wall of the tube is very thin and delicate, and does not appear to be composed of any ordinary cell-membrane. The staining shows that the granular substance of the interior really consists of a large number of delicate rod-like bodies. As the tube grows down the hair it maintains its own independence, and does not pass through the general thickness of the cells, in which it remains quite distinct and separate. After making its way into the interior, the intruder sets up a considerable hyper trophy of the tissue, causing the formation of a tubercle, which soon shows a certain amount of special structure, and the bacterial bodies are supplied to it. The rod-like bodies from the interior of the tube, which has considerable resemblance to the zoogloea of many Bacteria, are liberated into the interior of the cells of the tubercle and fill it, and are used as a preparation including plants such as clover, the root-hair is reached the invading tubes and their ramifications frequently disappear, leaving the cells full of the baciterioids, as they have been described. When the root-hair has been thus infected, the contents of the tube may be taken into the cells, and are then ready to infect new plants. In some cases the zoogloea thread or tube has not been seen, the organism consisting entirely of the bacterioids.
**PLANTS**

This peculiar relationship suggests at once a symbiosis, the Fungus gaining its nutriment mainly or entirely from the green plant, while the latter in some way or other is able to utilize the free nitrogen of the air, for the fixation of which it was long supposed that a special organ or apparatus had to be present, the function of which remained remains undecided. Two views are still receiving certain support, though the second of them appears the more probable. These are: (1) That the plant is not stimulated by the symbiotic organism, but leaves it entirely to its own devices, and is only able to fix the nitrogen or cause it to enter into combination. (2) That the fixation of the gas is carried out by the fungal organism either in the soil or in the plant, and the nitrogenous substance so produced is utilized by the latter, either by the whole organism or by the green plant. Certain evidence which supports this view will be referred to later.

Whichever opinion is held on this point, there seems no room for doubt that the fixation of the nitrogen is concerned only with the root, and that the green leaves take no part in it. The nodules, in particular, appear to play the important part in the process. Many plants, including those which produce the gaseous nitrogen into which we breathe, are capable of being assimilated by the protoplasm of the cells are not known. The energy for the purpose appears to be supplied by the oxidation of the molecules containing nitrogen, so that it is dependent upon such oxidation taking place. We have investigated this point with great care, and he has come to the conclusion that about 35 milligrams of nitrogen are oxidized for each milligramme of carbon absorbed and put to use.

**The Nitrification of Organic Matter in Plants and Animals.**—As we have seen, the tendency of recent research is to prove the identity of the mode of nutrition of vegetable and animal life. The method of nutrition and its treatment in the body is precisely similar. In both groups we find the presence of nutritive material in two forms, one specially fitted for transport, the other for storage. We have seen, too, that the concentration of these two processes is distinct, and the one manifestly can manufacture faster than those of consumption. We have the surplus sugar, for instance, deposited as starch in the chloroplasts themselves. The manufacture goes on very actively so long as the plant has access to this material, and the starch is seen, during the process, to be accumulating. We find the same phenomena when we look at the digestion of starch, alcurone grains, amorphous proteins, fats, etc., in the neighbourhood of growing points, cambium rings and phyllogens; also the more prolonged storage in tubers, stems and other reproductive parts. The formation of starch is seen in the visions in the storage of glycogen in the liver and other parts, of fat in various internal regions, and so on. In both we find the reserve of food, so far as it is in excess of immediate need, existing in two forms, the one being the most suitable for transport, and we see continually the transformation of the one into the other. The formation of the storage form at the expense of the travelling form is due to the activity of some protoplastic structures; it may be partial or total, and the transformation takes place in the process of secretion. The converse process is one of true digestion, which deserves the name no less because it is intracellular. We find processes of digestion strictly comparable to those of the alimentary canal of an animal in the case of the insectivorous Nymphitens, Drosera and other similar plants, and in the saprophytic Fungi. Those which now concern us recall the utilization of the glycogen of the liver, the stored fats and proteins of other parts of the animal body being like them intracellular.

**Enzymes.**—The agents which effect the digestive changes in plants have been studied with much care. They have been found to be more or less distinct from those by which the process takes place in animals. A vast number of them have been discovered and investigated, and the major role call for a brief notice. Their number, indeed, renders it necessary to classify them, and rather to look at groups of them than to examine them one by one. They are usually classified according to the materials on which they work, and we may here notice especially four principal groups, the members of which perform in the stomach or intestines the various processes of external digestion. These decompose respectively carbohydrates, glucosides, proteids and fats or oils. The action of the enzyme in nearly every case is one of hydration, the body acted upon is hydrolised into its elements and made to take up water and to undergo a subsequent decomposition.

Among those which act on carbohydrates the most important are:
- The two varieties of diastase, which convert starch into maltose or malt, and isomaltose, or maltose, which converts cane sugar into glucose (grape sugar) and fructose;
- Glucose or maltose, which produces grape sugar from maltose; and
- Cyathae, which hydrolyses cellulose. Another enzyme which does
not appear to be concerned with digestion so directly as the others is Prefix, which forms vegetable jelly from pectic substances occurring in the cell-walls.

The enzymes which act upon glucosides are many; the best known are emulsin and myrosin, which split up respectively amygdalin, the special product in plum plants, and sinigrin and other substances, which have a wide distribution among those of the Cruciferous group. Many enzymes of less frequent occurrence are erythrosyn, rhainose and gaulthieterin.

The proteolytic enzymes, or those which digest proteins, are usually divided into two groups, one which breaks down ordinary protiens into diffusible bodies, known as peptones, and which are themselves hydrolysed by peptidases, the second which breaks down the peptones into the amino-acids of which we have spoken before. This group is represented by the crepsin of the pancreas, the trypsin of the stomach, the peptidases of the other organs. At any rate, the evidence of the proteolytic enzymes, the trypsin of the pancreas, possesses the power of both conversion and condensation and relationships existing between these enzymes are still the subjects of experiment, and we cannot regard them as exhaustively examined. It is likely that many more proteolytic enzymes exist, although many trypsin have been discovered, and one form of crepsin, at least, is very widespread. Among the trypsin we have the papain of the Papaw fruit (Carica Papaya), the bromelin of the Pine-apple, and the enzymes present in many germinating seeds, in the seedlings of several plants, and in other parts. Another enzyme, rennet, which in the animal body is proteolytic, is frequently met with in plants, but the mode of action is not yet ascertained.

The digestion of fat or oil has been adequately investigated, and its decomposition in germinating seeds has been found to be due to an enzyme, which has been called lipase. It splits it into a fatty acid and glycerol, and the question is one of determining the form in which they attack, and have consequently been named oxidases. Very little is known about them.

In many cases the digestion of reserve food-materials is effected by the direct action of the proteolysins, the enzyme of a group containing similar substances, and including several plant enzymes. This property of living substance can be proved in the case of the cells of the higher plants, but it is especially prominent in the more lowly organisms, such as the Bacteria. The processes of respiration in these may be regarded as supplying the potential energy of such a power in the vegetable organisms. At the same time it must be remembered that the secretion of enzymes by Bacteria is of recent occurrence.

Supply and Distribution of Energy in Plants.—It is well known that one of the conditions of life is the maintenance of the process which is known as respiration. It is marked by the constant and continuous liberation of a certain volume of carbon dioxide and water vapour. There is no direct connexion between the two, the oxygen is absorbed almost immediately by the protoplasm, and appears to enter into some kind of chemical combination. The oxygen, however, is by no means an instance and is continually breaking down to a certain extent, giving rise to various substances of different degrees of complexity, some of which are again built up by it into its own substances, and other by the addition of carbon dioxide, which is necessary in the process of respiration. The oxygen and water are the most prominent. These respiratory processes are associated with the liberation of energy by the protoplasm, energy which it applies to various purposes. The assimilation of complex foods certainly may be regarded as supplying the protoplasm with a potential store of energy, as well as building up its substance. Whenever complex bodies are built up from simple ones we have an abstraction of energy in the form and its conversion into potential energy; whenever decomposition of complex bodies into simpler ones takes place we have the liberation of some or all of the energy that was used in their construction.

Some authors have been directed to the question of the supply, distribution and expenditure of energy in the vegetable kingdom. This is an extremely important question, since the supply of energy to the animal world has been found to depend upon the products of the vegetable kingdom. The energy of the sun is the radiant energy of the rays of the sun, and its absorption is mainly due to the properties of chlorophyll. This colouring matter, as shown by its absorption spectrum, picks out of the ordinary beam of light 27 per cent. of light of the green and 35 per cent. of the red, of which the green and yellow. This energy is obtained especially by the chloroplasts, and of that it is at once devoted to the construction of complex organic material, being thus turned from kinetic energy into potential chemical energy. Other processes, which are dependent partly upon the oxidation of the carbohydrates so formed, and therefore upon an expenditure of part of such energy, also mark the storage of energy into the potential store. Indeed, the process of protoplasm itself creates the same thing. Thus even in these constructive processes there occurs a constant passage of energy backwards and forwards from the kinetic to the potential condition and vice versa. The other constant in the process, however, is the fixation of a certain part of the radiant energy absorbed by the chlorophyll. The rays of the visible spectrum do not supply all the energy which the plant obtains. It has been suggested by several botanists, with which we have already dealt, that both visible or chemical rays can be absorbed and utilized by the protoplasm without the intervention of any pigment such as chlorophyll. There is no question concerning the existence of this power in the cells of the higher plants. We have observed that almost all the plants to avoid themselves of the heat rays. There is, however, a direct intertaction between the plant and the air, which in the case of heated bodies, is capable of absorption. In this case, the tendency to absorb heat in this way, either from the air or directly from the sunlight, has already been pointed out as a danger which needs to be averted by transpiration.

The question of the distribution of this stored energy to the separate protoplasts of the plant can be seen to be the same problem as the distribution of the food. The material and the energy go together, the decompositition of the one is accompanied by that of the other, which is used at once in the vital processes of the cell, being in fact largely employed in constructing protoplasm or storing various products. The actual liberation in any cell is only partial, and generally takes the form of heat. The metabolic changes in the cells, however, concern other decompositions side by side with those which involve the building up of protoplasm from the substances of which it is composed. So if the situation be different in the case of plants, the living substance is the seat of transformations which are continually proceeding, being partially decomposed and again constructed, the new food being incorporated into it. The changes involve a continuous series of decompositions, the oxidation of the protoplasm and the oxidation of the substances it contains. The need of the protoplasm for oxygen has already been pointed out; in its absence death soon supervenes, respiration being stopped. Respiration, indeed, is the expression of the liberation of the potential energy of the protoplasm itself. It is not certain how far substances in the protoplasm are directly oxidized with the liberation of heat, but it is in the nature of the case that this appears to take place. Even their oxidation, however, is effected by the protoplasm acting as an oxygen carrier.

The supply of oxygen to a plant is thus seen to be as directly connected with its life as the supply of food. The production of oxygen is therefore a necessary part of the food concerned in its nutrition. If the access of oxygen to a protoplasm is interfered with its normal respiration soon ceases, but frequently other changes supervene. The partial asphyxiation of a plant is similar to the operation of the lung to set up a new and permanent supply of oxygen.
plants

If we consider the behaviour of a growing organ such as a root, we find that, like a cell, it shows a grand period of growth. Just behind its apex the cells are found to be all in process of active division and a great apex of growth takes place. But the quantum of protoplasm, for the cells divide again as soon as they have reached a certain size. As new cells are continually formed in the meristematic mass those which are farthest from the apex gradually shrink and a tongue of dry and degenerate protoplasm advances, which is associated more particularly with the formation of the vacuoles, consequent upon the establishment of considerable hydrostatic pressures in them, thus causing the bulk of the cells to be greatly enlarged. Here it is that the actual extension in length of the root takes place, and the cells reach the maximum point of the grand period. They then gradually lose the power of growth, the oldest protoplasts nearest from the apex parting with it first, and they pass gradually over into the condition of the permanent tissues.

The same order of events may be ascertained to take place in the stem; but in this region it is complicated by the occurrence of nodes and internodes, growth in length being on certain occasions checked by growth in circumference, which may be growing simultaneously. The region of growth in the stem is, as a rule, much longer than that of the root. The growth of the leaf is at first apical, but this is not very prolonged, and the subsequent enlargement is due to an intercalary growing region near the base.

The turgidity in the cells of a growing member is not uniform, but shows a fairly rhythmic variation in its different parts. If the member one which absorbs water, such as a leaf, the two sides frequently show a difference of degree of turgidity, and consequently of rate of growth. If we consider a cylinder of growing tissues, we shall find that the smaller protoplasts, which are closely packed, are slowest to grow; so that it closely rolled up, the upper or ventral surface being quite concealed. As it gets older it gradually unfolds and expands into the adult form. This is due to the fact that while young the turgidity and protoplasm are such that the dorsal side is the first to grow, and then it becomes rolled up. As it develops the maximum turgidity and growth change to its upper side, and so it becomes unfolded or expanded. These two conditions are generally described under the names of hypostem and exostem respectively.

Cylindrical organs may exhibit similar phenomena. One side of a stem may be more turgid than the opposite one, and the maximum turgidity, with its consequent growth, may alternate between two opposite sides. The growth of a root may alternate. If it be bent the extension on one side in those surroundings and the consequent changes a plant must encounter, it appears obvious that interaction and adjustment between the plant and its environment must be constant and well balanced. That such adjustment shall take place postulates on the part of the plant a kind of perception or appreciation of the changing conditions which affect it.

Careful examination soon shows an observer that such perceptions exist, and that they are followed by certain purposeful changes in the plant, sometimes mechanical, sometimes chemical, the object being evidently to secure some advantage for the plant, to ward off some danger, or to extricate it from extreme difficulty. We may speak, indeed, of the plant as possessed of a rudimentary nervous system, by the aid of which the necessary adjustments are brought about. The most constantly occurring changes that beset a plant are connected with illumination, temperature, moisture, and contact with foreign bodies. Setting aside other susceptibilities, we have evidence that most plants are sensitive to all these.

If a growing stem receives stronger illumination on one side than another, its apex slowly turns from the vertical in the direction of the light source, continuing its change of position until it is in a direct line with the incident rays. If a root is similarly illuminated, a similar change of direction of growth follows, but
in this case the organ grows away from the light. These movements are spoken of as heliotropic and apheliotropic curvatures. The purpose of the movement is to bear out the perception that the plant is trying to adjust itself to its environment. The stem, by pointing directly to the light source, secures the best illumination possible for all of its leaves, the latter being distributed symmetrically around it. The root is made to press its way into the darker cracks and crannies of the soil, so bringing its root-hairs into better contact with the particles round which the hygroscopic water hangs. Leaves respond in another way to the same influence, placing themselves across the path of the beam of light.

Similar sensitiveness can be demonstrated in other cases. When a root comes in contact at its tip with some hard body, such as might arise in progress, a curvature of the growing part is set up, which takes the young tip away from the stone, or what-not, with which it is in contact. When a sensitive tendril comes into contact with a foreign body, its growth becomes so modified that it twines round it. Many instances might be given of appreciation of and response to other changes in the environment by the growing parts of plants; among them we may mention the opening and closing of flowers during the days of their expansion. One somewhat similar phenomenon, differing in a few respects, marks the relation of the plant to the attraction of gravity. Observation of germinating seedlings makes it clear that sometimes they have a perception of the direction of gravity. The young roots grow vertically downwards, the young stems vertically upwards. Any attempt to interfere with these directions, by placing the seedlings in abnormal positions, is frustrated by the seedlings themselves, which change their direction of growth by bringing about curvatures of the different parts of their axes, so that the root soon grows vertically downward again and the stem in the opposite direction. Other and older plants give evidence of the same perception, though they do not respond all in the same way. Speaking generally, stems grow upwards and roots downwards. But some stems grow parallel to the surface of the soil, while the branches both of stems and roots tend to grow at a definite angle to the main axis from which they come. These movements are spoken of as different kinds of geotropic curvatures. This power of perception and response is not by any means confined to the growing organs, though in these it is especially striking, and plays a very evident part in the disposition of the growing organs in advantageous positions. It can, however, be seen in adult organs, though instances are less numerous.

When the pinnate leaf of a Mimosa pudica, the so-called sensitive plant, is pinched or struck, the leaf droops rapidly and the leaflets become approximated together, so that their upper surface is against each other. The extent to which the disturbance spreads depends on the violence of the stimulation—it may be confined to a few leaflets or it may extend to all the leaves of the plant.

The leaves and leaflets of many plants, e.g. the telegraph plant, Desmodium gyrans, behave in a similar way under the stimulus of approaching darkness. A peculiar sensitiveness is manifested by the leaves of the so-called insectivorous plants. In the case of Dionaea muscipula we find a two-lobed lamina, the two lobes being connected by a midrib, which can play the part of a kind of hinge. Six sensitive hairs spring from the upper surface of the lobes, three from each; when one of these is touched the two lobes rapidly close, bringing their upper surfaces into contact and imprisoning anything which for the moment is between them. The mechanism is applied to the capture of insects alighting on the leaf.

Drosera, another of this insectivorous group, has leaves which are furnished with long glandular tentacles. When these are excited by the settling of an insect on the leaf they slowly bend over and imprison the intruder, which is detained there meanwhile by a sticky excretion poured out by the glands.

In both these cases the stimulation is followed, not only by movement, but by the secretion of an acid liquid containing a digestive juice, by virtue of which the insect is digested after being killed.

The purposeful character of all these movements or changes of position indicates that they are of nervous origin. We have in them evidence of two factors, a perception of some feature of the environment and following this, after a longer or shorter interval, a response calculated to secure some advantage to the responding organ. We find on further investigation that these two conditions are traceable to different parts of the organs concerned. The perception of the changes, or, in other words, the reception of the stimulus, is associated for example, with the tips of roots and the apices of stems. The first recognition of a specially receptive part was made by Charles Darwin, who identified the perception of stimulation with the tip of the young growing root. Amputation of this part involved the cessation of the response, even when the conditions normally causing the stimulation were maintained. It later demonstrated that the tips of the plumes of grasses were sensitive parts. The responding part is situated some little distance farther back, being in fact the region where growth is active. This bending part has been proved to be insensitive to the stimuli. There is consequently a transmission of the stimulus from the sensitive organ to a kind of motor mechanism situated some little way off. We find thus three factors of a nervous mechanism present, a receptive, a conducting, and a responding part. The differentiation of the plant's substance so indicated is, however, problematical. It is by no means uncommon to find that the cells of these regions that can be associated with the features of the stimulus have properties they possess. Even the root tip, which shows a certain differentiation into root cap and root apex, cannot be said to be a definite sense organ in the same way as the sense organs of an animal. The root is continually growing and so the sensitive part is continually changing its composition, cells being formed, growing and becoming permanent tissue. The cells of the tip at any given moment may be sensitive, but in a few days the power of receiving the stimulus has passed to other and younger cells which then constitute the tip. The power of appreciating the environment is therefore to be associated with the protoplasm at the particular stage of its development and is transitory in its character.

What the nature of the stimulus is we are not able to say. The protoplasm is sensitive to particular influences, perhaps of vibration, or of contact or of chemical action. We can imagine though perhaps only vaguely, the way in which light, temperature, moisture, contact, &c., can affect it. The perception of direction or the influence of gravity presents greater difficulty, as we have no clear idea of the form which the force of gravity takes. Recently some investigations by Haberlandt, Noll, Darwin and others have suggested an explanation which has much to recommend it. The sensitive cells must clearly be influenced in some way by weight—not the weight of external organs but of some weight within them. This may possibly be the cell sap in their interior, which must exercise a slightly different hydrostatic pressure on the basal and the lateral walls of the cells. Or more probably it may be the weight of definite particular structures in their vacuoles. Many experiments point to certain small grains of starch which are capable of displacement as the position of the cell is altered. Such small granules have been observed in the sensitive cells, and there is an evident correlation between these and the power of receiving the protoplasmic stimuli. It has been shown that if the cell containing them is shaken for some time, so that the contact between them and the protoplasm of the cells is emphasized, the stimulus becomes more efficient in producing movement. This reduces the stimulus to one of contact, which is in harmony with the observations made upon roots similarly stimulated from the exterior. The stimulating particles, whether starch grains in all cases, or other particles as well, have been termed statoliths.

We have spoken of the absence of structural differentiation in the sense organs. There is a similar difficulty in tracing the paths by which the impulses are transmitted to the growing and curving regions. The conclusion of such stimulation to parts removed some distance from the sense organ suggests paths of transmission comparable to those which transmit nervous
impulses in animals. Again, the degree of differentiation is
very slight anatomically, but delicate protoplasmic threads have
been shown to extend through all cell-walls, connecting together
all the protoplasts of a plant. These may well serve as con-
ductors of nervous impulses. The nervous mechanism thus
formed is very rudimentary, but in an organism the conditions
of whose life render locomotion impossible great elaboration
would seem superfluous. There is, however, very great delicacy
of perception or appreciation on the part of the sense organ,
stimuli being responded to which are quite incapable of
impressing themselves upon the most highly differentiated
animal.

The power of response is seen most easily in the case of young
growing organs, and the parts which show the motor mechanism
are mainly the young growing cells. We do not find their
behaviour like that of the motor mechanism of an animal. The
active contraction of muscular tissue has no counterpart in the
plant. The peculiarity of the protoplasm in almost every cell
is that it is especially active in the regulation of its permeability
by water. Under different conditions it can retain it more
strongly or allow it to escape more freely. This regulation of
turgor is characteristic of vegetable protoplasm as contraction
of muscle. The response to the stimulus takes the form of
increasing the permeability of particular cells of the growing
structures, and so modifying the degree of the turgidity that is
the precursor of growth in them. The extent of the area affected
and of the variation in the turgor depends upon many circum-
stances, but we have no doubt that in the process of modifying
its own permeability by some molecular change we have the
counterpart of muscular contractibility.

The response made by the adult parts of plants, to which
reference has been made, is brought about by a mechanism
similar in nature though rather differently applied. If the leaf of
Mimosa or Desmodium be examined, it will be seen that at
the base of each leaflet and each leaf, just at the junction with
the respective axes, is a swelling known as a pulvinus. This has
a large lateral sort of parenchyma on its upper and lower sides. In
the erect position of the leaf the lower side has its cells extremely turgid,
and the pulvinus thus forms a cushion, holding up the petiole. On stimulation these cells
part with their water, the lower side of the organ becomes flaccid
and the weight of the leaf causes it to fall. The small pulvini of
the leaflets, by similar changes of the distribution of turgidity,
take up their respective positions after receiving the stimulus.
In some cases the two sides of the pulvini vary their turgidity
in turns; in others only the lower side becomes modified.

Similar turgescence changes, taking place with similar rapidity
in the midrib of the leaf of Dianoea, explain the closing of the
lobes upon their hinge. More slowly, but yet in the same way,
we may note the change in turgidity of certain cells of the
Drosa tentacles, as they close over the imprisoned insect.

Organic Rhythm.—It is a remarkable fact that during the
process of growth we meet with rhythmic variation of such
turgidity. The existence of rhythm of this kind has been ob-
served and studied with some completeness. It is the immediate
cause of the phenomena of circumnutation, each cell of the
circumnutating organ showing a rhythmic enlargement and
decrease of its dimensions, due to the admission of more and less
water into its interior. The restraint of the protoplasm changes
gradually and rhythmically. The sequence of the phases of the
rhythm of the various cells are co-ordinated to produce the
movement. Nor is it only in growing organs that the rhythm
can be observed, for many plants exhibit it during a much
longer period than that of growth. It is easy to realize how such a
rhythm may be produced by the application of stimuli, and can
consequently serve as the basis for the movement of the stimu-
lated organ. This rhythmic affection of vegetable protoplasm
can be observed in very many of its functions. What have been
described as "periodicities," such as the daily variations of
root-pressure, afford familiar instances of it. It reminds us of
a similar property of animal protoplasm which finds its expression
in the rhythmic beat of the heart and other phenomena.

PATHOLOGY OF PLANTS

("Phytopathology" or plant pathology (Gr. φυτοπαθήσις), comprises our knowledge of the symptoms, course, causes and
remedies of the maladies which threaten the life of plants, or
which result in abnormalities of structure that are regarded,
in the extreme case, as directly injurious to the existence of plants, not to life, as unsightly or undesirable. In its systematized form, as a branch of botanical study,
it is of recent date, and, as now understood, the subject first
received special attention about 1850, when the nature of
parasitism began to be intelligible; but many disjointed refer-
cences to diseased conditions of plants had appeared long before
this. The existence of blights and mildews of cereals had been
observed and recorded in very ancient times, as witness the Bible,
where half a dozen references to such scourges occur in the Old
Testament alone. The epidemic nature of wheat-rust was
known to Aristotle about 350 B.C., and the Greeks and Romans
knew these epidemics well, their philosophers having shrewd
speculations as to causes, while the people held characteristic
superstitions as to natural agents which was regarded of benefit in the dedication of special festivals and deities to the pests. Plant
knowledge flies emerge from galls. The few records during the middle
ages are borne out by what is known of famines and pestilence.
Shakespeare's reference in King Lear (Act III, sc. iv.) may be
equated in acquaintance with mildew in the 17th century, as also
the interesting Rouen law of Loverdo (1660). Malpighi
in 1679 gave excellent figures and accounts of leaf-rolling
and gall insects, and Grew in 1682 equally good descriptions of a leaf-
mining caterpillar. During the 18th century more academic
characteristic of treatment of the subject began to replace the scattered
notions. Hales (1727-1733) discussed the rotting of wounds, cankers, &c.,
but much had to be done with the microscope before any real
progress was possible, and it is easily intelligible that until
the theory of nutrition of the higher plants had been founded by
the work of Ingenhous, Priestley and De Saussure, the way was not
even prepared for accurate knowledge of cryptogamic parasites
and the diseases they induce. It was not till De Bary (1866)
made known the true nature of parasitic Fungi, based on his
researches between 1853-1865, that the vast domain of epidemic
diseases of plants was opened up to fruitful investigation, and
such modern treatises as those of Frank (1880 and 1895), Sorauer
(1886), Kirchner (1890), were gradually made possible.

Plant pathology embraces several branches of study, and may
be conveniently divided as follows:

1. The observation and accurate description of symptoms
(Diagnosis).
2. The study of causes or agencies inducing disease (Aetiology).
3. The practice of preventive and remedial measures (Thera-
petica).

In plants, however, the symptoms of disease are apt to exhibit
themselves in a very general manner. Our perceptions differ-
titate but imperfectly symptoms which are due to very different
causes and reactions, probably because the organization of the
plant is so much less highly specialized than that of higher
animals. The yellowing and subsequent casting of leaves, for
instance, is a very general symptom of disease in plants, and may
be induced by drought, extremes of temperature, insufficient or
excessive illumination, excess of water at the roots, the action of
tropical Fungi, insects, worms, &c., or of poisonous gases, and so forth;
and extreme caution, which are also in the new description
of such symptoms, especially when the untrained eye has taken no cognizance of, or has only vaguely observed, the
numerous collateral circumstances of the case.

The causes of disease may be provisionally classified somewhat
as follows, but it may be remarked at the outset that no one of
PLANTS

PATHOLOGY]

these proximal causes, or agents, is ever solely responsible;
is very easy to err in attributing a diseased condition to

and

any

it

of

them, unless the relative importance of primary and subordinate
agencies is discoverable. For instance, a Fungus epidemic is
impossible unless the climatic conditions are such as to favour
the dispersal and germination of the spores; and when plants are
killed off owing to the supersaturation of the soil with
water, it
is by no means obvious whether the excess of water and dissolved
materials, or the exclusion of oxygen from the root-hairs, or the
lowering of the temperature, or the accumulation of foul products
of decomposition should be put into the foreground. In every
case there are chains of causation concerned, and the

same

be differently grouped in different cases.
Bearing in mind these precautions, we

While such a

classification may serve its purpose as a sort of
index, it must be confessed that the limits of its usefulness are
soon reached. In the first place, the so-called '' internal causes "
of disease is probably a mere phrase covering our ignorance of the

factors at work, and although a certain convenience attaches
to the distinction between those cases where tender breeds of

plants apparently exhibit internal predisposition to suffer more
readily than others from parasites, low temperatures, excessive
growth, &c. as is the case with some grafted plants, cultivated

environment, living and non-living.

The Vertebrata come within the scope of our subject, chiefly as
destructive agents which cause wounds or devour young shoots
and foliage, &c. Rabbits and other burrowing animals injure
roots, squirrels and birds snip off buds, horned cattle strip off bark,
and so forth. It is among the Invertebrata that epidemics of
destruction are referred to, though we should bear in mind that
it is only the difference in numerical proportion that prevents our
speaking of an epidemic of elephants or of rabbits, though we use
the term when speaking of blight insects; there is little consistency
in the matter, as it is usual to
speak of an invasion or scourge of
Insect injuries are very varied in degree
locusts, caterpillars, &c.
and in kind. Locusts devour all before them caterpillars defoliate
the plant, and necessitate the premature utilization of its reserves;
other insects (e.g. Grapholitha) eat the buds or the roots (e.g. wireworms), and so maim the plant that its foliage suffers from want
of water and assimilation is diminished, or actual withering follows.
Many aphides, &c., puncture the leaves, suck out the sap, and
induce va/ious local deformations, arrest of growth, pustular
swellings, &c., and if numerous all the evils of defoliation may
follow.
Others (e.g. miners) tunnel into the leaf parenchyma,
and so put the assimilating areas out of action in another way.
It should be remembered that a single complete defoliation of a
herbaceous annual may so incapacitate the assimilation that no
stores are available for seeds, tubers, &c., for another year, or at
most so little that feeble plants only come up. In the case of a
tree matters run somewhat differently; most large trees in full
foliage have far more assimilatory surface than is immediately
necessary, and if the injury is confined to a single year it may be
a small event in the life of the tree, but if repeated the cambium,
bud-stores and fruiting may all suffer.
Many larvae of beetles,
moths, &c., bore into bark, and injure the cambium, or even the
wood and pith; in addition to direct injury, the interference with
the transpiration current and the access of other parasites through
the wounds are also to be feared in proportion to the numbers of
insects at work.
Various local hypertrophies, including galls,
result from the increased growth of young tissues irritated by the
punctures of insects, or by the presence of eggs or larvae left behind.
They may occur on all parts, buds, leaves, stems or roots, as shown
by the numerous species of Cynips on oak, Phylloxera on vines, &c.
The local damage is small, but the general injury to assimilation,
absorption and other functions, may be important if the numbers
In addition to insects, various kinds of worms, molluscs,
increase.
The so-called eel&c., are sometimes of importance as pests.
worms (Nematodes) may do immense damage on roots and in
the grains of cereals, and every one knows how predatory slugs
and snails are. (See ECONOMIC ENTOMOLOGY.)
Plants as agents of damage and disease may be divided into
those larger forms which as weeds, epiphytes and so forth, doinjury by dominating and shading more delicate species, or by
gradually exhausting the soil, &c., and true parasites which actually
live on and in the tissues of the plants.
It must be remembered
that phanerogams also include parasitic species e.g. Cuscuta,
Loranthus, Viscum, Thesium, Rhinanthus, &c. with various capacities for injury.
These enemies are as a rule so conspicuous that

equilibrium.

I.
Passing to the recognized external agencies, the physical
condition of the soil is a fruitful source of disease. If too closely
packed, the soil particles present mechanical obstacles to growth;
if too retentive of moisture, the root-hairs suffer, as already hinted
All
if too open or over-drained, the plant succumbs to drought.
those properties of soil known as texture, porosity, depth, inclination to the horizon, &c., are concerned here.
Many maladies of
plants are traceable to the chemical composition of soils e.g.
deficiency of nutritive salts, especially nitrates and phosphates;
the presence of poisonous salts of iron, copper, &c., or (in the soil
about the roots of trees in towns) of coal-gas and so forth. But
it is worthy of special attention that the mere chemical composition of agricultural and garden soils is, as a rule, the least important feature about them, popular opinion to the contrary
will almost always provide the
notwithstanding. Ordinary soils
necessary chemical ingredients if of proper physical texture, depth,
&c. (see FUNGI and BACTERIOLOGY).
As regards water, its deficiency or excess is a relative matter, and
although many of the minor maladies of pot-plants in windows
and greenhouses controlled by amateurs depend on its misuse,
Its
water alone is probably never a primary cause of disease.
over-supply is, however, a frequent cause of predisposition to the
attacks of parasitic Fungi e.g. the damping off "of seedlings and
in saturated soils not only are the roots and root-hairs killed by
course of soil fermentation is altered,

illumination.
The drawn or
optimum
etiolated condition of over-shaded plants is a case in point, though
here again the soft, watery plant often really succumbs to other
disease agents e.g. parasitic Fungi supervening on its nonresistant condition.
Animals and plants as agents of disease or injury form part of
the larger subject of the struggle for existence between living
organisms, as is recognized even by those who do not so readily
apprehend that diseased conditions in general are always signs of
defeat in the struggle for existence between the suffering organism

constrained to carry out its functions of
germination, growth, nutrition, reproduction, &c., between certain
limits of temperature, and somewhere between the extremes of
these limits each function finds an
optimum temperature at which
the working of the living machinery is at its best, and, other things
being equal, any great departure from this may induce pathological
conditions; and many disasters are due to the failure to provide
such suitable temperatures e.g. in greenhouses where plants
requiring very different optimum temperatures and illumination
are kept together. Equally disastrous are those climatic or seasonal
changes which involve temperatures in themselves not excessive
but in wrong sequence; how many more useful plants could be
grown in the open in the United Kingdom if the deceptively mild
springs were not so often followed by frosts in May and June!
The indirect effects of temperature are also important. Trees, of
which the young buds are " nipped " by frost, would frequently
not suffer material injury, were it not that the small frost-cracks
serve as points of entry for Fungi; and numerous cases are known
where even high temperatures can be endured on rich, deep, retentive soils by plants which at once succumb to drought on shallow
or non-retentive soils.
All chlorophyll plants require light, but in very different degrees,
as exemplified even in the United Kingdom by the shade-bearing
beech and yew contrasted with the Tight-demanding larch ana
birch and as with temperature so with light, every plant and even

light.

is a cause of disease in the neighbourhood of
chemical works, large towns, volcanoes, &c., in so far as it carries
acid gases and poisons to the leaves and roots; but it is usual to
associate with it the action of excessive humidity' which brings
about those tender watery and more or less etiolated conditions
which favour parasitic Fungi, and diminish transpiration and therefore nutrition.
It is customary to speak of the disastrous effects
of cold winds, snow, hail and frost, lightning, &c., under the heading
of atmospheric influences, which only shows once more how impossible it is to separate causes individually.
Turning to the non-material external agents, probably no factors
are more responsible for ill-health in plants than temperature and


we do not look on their depredations as diseases, though the gradual deterioration of hay under the exhausting effects of the leaf-restrainers like Rhinanthus, and the onslaught of Cuscuta when unduly abundant, should teach us how unimportant to the definition the question of size may be.

If, however, among the Fungi that we find the most disastrous and elusive agents of disease. Parasitic Fungi may be, as regards their direct action, purely local—e.g. Schizina, which forms gall-like tumours on the petioles of plants of the Bedstraw family. Such excreences on juniper stems; numerous leaf Fungi such as Puccinia, Aecidium, Septoria, &c., causing yellow, brown or black spots on leaves; or Ustilago in the anthers of certain flowers. In such cases the immediate damage done may be suggested by the effects of prolonged action and the summation of numerous attacks at different points, at certain times now frequent, certain others being rare, and rampant, and, instead of a local effect, exerts a general de-structive action throughout the plant—e.g. Pythium, which causes the "damping off" of seedlings, reducing them to a putrid mass in a few days. Many Fungi, in themselves not very aggressive, slowly bring about important and far-reaching secondary effects. Thus, many Hymeno-myces (Agarics, Porphorei, &c.) live on the wood of trees. This wood is slowly, but pervasively decomposed. One part of the Fungus gradually invades the vessels occupied with the transmission of water up the trunk, cuts off the current, and so kills the tree; in other cases it destroys the connexions between the leaves and the roots. The root's ability to obtain oxygen, resulting in "foulng." Numerous Fungi, though conspicuous as parasites, cannot be said to do much individual injury to the host. The extra-molecular malformations known as "witches'-brooms," are caused by the production of tufts of twigs in which the mycelium of Eosacous (or birch) or Aecidium (on silver fir) are living, may be borne in considerable numbers for years without any very extensive apparent injury to the tree. Again, the curious distortions on the stems of nettles attacked by the Aecidium form of the heteroecous Puccinia Curtis (see Fungi for Heterocercum), or on maize stems and leaves attacked by Ustilago Maydis, or on the inflorescence of crucifers infected with Cystopus, &c., are not individually very destructive; it is the cumulative effects of numerous attacks or of extensive epidemics which eventually tell. Some very curious details are observable in these cases of malformation. For instance, the Aecidium cells, though numerous, are so small that to decipher their position, duration and arrangement, and even shape of foliage leaves from the normal; and the shoots of Urophora infected with the acelia of Uromyes Fusiformis develop a normal stem; so that the plants have been taken for different species. Similarly with Anemone infected with Puccinia and Vascularum with Calypotispora, and many other cases of deformations due to hypertrophy or atrophy. In-stances of very large cells may term tolerated parasitism, where the host-plant seems to accommodate itself very well to the presence of the Fungus, paying the tax it extorts and nevertheless not sickening but managing to provide itself with sufficient material to go on with, and to the other plant systems to breach the mutual accommodation between host and guest has been carried so far that each derives some benefit from the association—symbiosis (see Fungi).

II. The kinds of disease due to these various agencies are very different. A plant may be diseased as a whole, because nearly all its tissues are in a morbid or pathological condition, owing to some Fungus pervading the whole—e.g. Pythium in seedlings—or to a portion of it, and perhaps the agent of that portion disease—e.g. an alga infected with a Chytridium—indeed, matters can hardly be otherwise. But the case is obviously different where a plant dies because some essential organ or tissue has been destroyed, and other parts have suffered because supplies are cut off—e.g. when the upper parts of a tree die off owing to destruction of the roots, or to the ringing of the stem lower down, and the consequent interference with the ascension of water. In a large number of cases, however, the disease is purely local, and does not itself extend far into the organ or tissue affected.

If a mass of living plant-tissue is cut, the first change observed is one of colour: the white "flesh" of a potato or an apple turns brown as the air enters, and closer examination shows that cell walls and contents are alike affected. The cut cells die, and oxidized products are concerned in the change of colour, the brown juices extend into the original tissue and the cell-walls are loosened, and available after some hours is that the uncutched cells below the cut grow larger, push up the dead surface, and divide by walls tangential to it, with the formation of tabulated cork-cells. The layer of cork thus formed is permeated by the air, and the consequence is that uninjured cells below. Such healing by cork formation is accompanied by a rise of temperature: the active growth of the dividing cells causes a great loosening of the tissues, and a state of "wound fever" supervenes until the healing is completed. The phenomena described occur in all cases of cicatrization of wounds in nature—e.g. leaf-tissue, young stems, roots, &c., when cut, and in the case of a piece of cork cut from the bark, observed in the occlusion of broken twigs and of falling leaves, and it is from the actively growing "callus" developed at the surface of the wounded tissues of cuttings, budding, prunings, &c., that the healing and renewal of tissues occur of which advantage is taken in the practice of what might well be termed plant surgery. Cases of cicatrization are numerous, and almost everywhere a parasitic organism gains access to a cell—e.g. Pleotrichels causes the invaded Pilobolas to swell up, and changes the whole course of its cell metabolism, and similarly with Plasmodiophora in the root-tissues, and many other aspergilli, and where irritation and hypertrophy of cells are common signs of the presence of parasites, as evinced by the numerous malformations, galls, witches'-brooms, &c., on diseased plants. The now well-known fact that a small drop of water placed on a Fungus is capable of living protoplasm, and that respiratory activity and growth may be accelerated by chloriform, ether and even powerfull mineral poisons, such as mercuric chloride, in minimal doses, offers some explanation of these phenomena of hypertrophy, and, as the irritations and other responses to the presence of irritant agents. Still further insight is afforded by our increasing knowledge of the enzymes, and it is to be remarked that both poisons and enzymes are very common in just such parasitic Fungi as induce discolorations, hypertrophies and the death of cells—e.g. Botrytis, Ergot, &c.

Now it is clear that if an organism gains access to all parts of a plant, and may even penetrate to the very living protoplasm which isomerizes, we may have the latter behaving abnormally—i.e. it may be diseased throughout; and such actual cases occur in the case of Urophora pervaded with Uromyes Fusiformis, the presence of which alters the whole aspect of the infected part, lengthening, branching, and growing. But though further, every cell may be killed and the plant forthwith destroyed—e.g. Pityohithor in potatoes. If, on the other hand, the irritating local agent is itself in action, causing only a few cells to react, we have the various pinicles, excreences, outgrowths, &c., exhibiting similar effects, such as Ustilago Maydis on the maize, various galls, witches'-brooms, &c.

It must not be overlooked that the living cells of the plant react upon the parasite as well as to all external agencies, and the picture of disease becomes intelligible only if we bear in mind that it consists in such altered metabolism—deflected physiology—as here happens. The removal of the cells is the primary consequence of a heat-damage, and if, on the contrary, the gradual cooling is met by a corresponding depletion of the cells of water, even intense cold may be sustained without injury.

Or, take another case. If the attack of a parasite is met by the formation of some substance in the protoplasm which is chemotherapeutically repulsive to the invader, it may be totally incapable of penetrating the cell, even though equipped with a whole armory of artifices to enable it to withstand the host-cell's retaliations. This is the case where we should easily overcome the more passive resistances offered by mere cell-walls and cell-contents of other plants, the protoplasm of which forms bodies chemotherapeutically attractive to the Fungus.

The various degrees are completely explained by the foregoing. In order that a Fungus may enter a plant, it must be able to overcome not merely the resistance of cell-walls, but that of the living protoplasm; if it cannot do this, it must remain for all practical purposes an impenetrable parasite, as is the case with other parasites, e.g. Vagner, Heteromyces, &c., and, at most, vegetate in the intercellular spaces and anchor itself to the cell-walls, e.g. Trichosporium. The inability to enter the cells due to the lack of chemotrophic bodies, to incapacity to form cellulose-dissolving enzymes, to the existence in the host-cells of antagonistic bodies which neutralize or destroy the acids, enzymes or poisons formed by the hyphae, or even to the formation of these bodies themselves, may be the cause of the disease arising in cases, when inside it does not follow that the Fungus can kill the cell, and many cases are known where the Fungus can break through the cell's first lines of defence (cell-wall and protoplastic lining); but the struggle then goes on as a fight for the control in the cell, the bilberries, and flies convey the conidia of ergot from plant to gnats. Insects, indeed, are largely concerned in disseminating Fungi, either on their bodies or via the alimentary canal. Worms bring poisons to the surface of soil, ducks and other birds convey them on their muddy feet, and, as is well-known, wind and other physical
PLANTS

Symptoms, but for the purposes of classification in an article of this scope we shall only attempt to group the various cases under the more obvious signs of disease exhibited.

Some of the symptoms are among the commonest of all signs that a plant is "sickly". In their presence to the prying eye and the touch. The plant usually has a faint appearance. It may be insufficient illumination (Etiolation), as seen in geraniums kept ina window, or it may be due to a poor growth of certain parts, and the stems may be short and thick. Lack of water may also be accompanied by wilting. Over-watering may be due to drought. Over-transplantation in bright wintry weather, when the roots are not absorbing, often results in yellowing. In other cases the presence of insects, Fungi or poisons at the time of diurnal life features, may be looked for. All plants with which variegated foliage may be considered, concerns a different set of causes, still obscure, and usually regarded as internal, though experiments go to show that some variegations are infectious.

PATHOLOGY

PRINCIPLES

In plants, as in man, the days of the life may be inscribed by the appearance of certain symptoms. Thus the young spores of a Fungus, or insect, hitherto leading a quiet endame life in the fields and forests, large tracts of its special food, along which it may range rampant without check to its dispersal, nutrition and reproduction of the pest, and the lesson to be learnt is that pests are established in the wild and that control must be sought. Nevertheless, epidemics occur, and practical measures are devised to meet the various cases and to check the ravages of the pest. The problem consists in most cases in spraying the affected plants with poisons, or emulsions in oil or dusting them with fungicidal or insecticidal powders, or applying the fumes of lethal gases. For the composition of the numerous lives of pests, the practical worker will be guided by the following principles apply generally. The poison must not be strong enough to injure the roots, leaves, &c., of the host-plant, or allowed to act long enough to bring about such injury. Care and intelligence are especially needed with certain insects such as poisonous gases, or the operators may suffer. It is worse than useless to apply drastic remedies if the main facts of the life-histery of the pest are not known; e.g., the application of ordinary acid and alkali to the invertebrates of the potato, or the application of a bluish wine to a session may cause the pest to become easily apparent. If the spores, or Usdago, is growing can only result in failure, and similarly if tobacco fumes, for instance, are applied when the insects concern themselves to the ground beneath. Similar applications at the moment when spores are shed or on the leaves, or stems, or roots, of hosts, Peronospora, or to the young mycelia of epidemical parasites, e.g., Erysiphe, or the sweeping in hot water of thoroughly ripe hard grains to obtain the grain-setters, e.g., Zymcury, or the use of a solution of hydrocyanic acid gas when young insects are commencing their ravages, e.g., Red-spider—all these and similar procedures timed to catch the pest at a vulnerable stage are intelligent and predictable prophylactic measures, as has been repeatedly shown.

Numerous special methods of preventing the spread of Fungi, or the migrations of insects, or of trapping various animals; of leaving infected ground fallow, or of growing another crop useless to the pests or fattening cattle in the fields, are among the more indirect methods, such as the grafting of less resistant scions on more vigorous stocks, of raising special late or early varieties by crossing or selection, and so on, have also met with success; but it must be remembered that such control is meant to cover what means that some peculiarity of quick growth, early ripening or other life-features in the plant is for the time being taken advantage of. For instance, in the case of insects, the feeding cells of the insect can also be applied for defensive purposes, and to co-operate in this formation of regenerative tissue, and if the wound is a mere knife-cut in the "bar", the protruding lips of callus formed at the edges of the wound soon meet, and the slit is healed up by the tissue growing out and filling the space. That the encouragement of insectivorous birds has been profitable is well established, and it is equally well-known that their destruction may lead to disastrous insect plagues.

Diseases and Symptoms.—The symptoms of plant diseases are, as already said, apt to be very general in their nature, and are sometimes so vaguely defined that little can be learned from them as to the causes at work. We may often distinguish between primary symptoms and secondary or subordinate symptoms.
wounds due to plants which entwine, pierce or otherwise materially injure trees, &c., on a large scale.

2. Pustular Growths more or less abnormal in character, are frequent signs of diseased organs. They are due to hyperrophy of young tissues, which may undergo profound alterations simultaneously, and occur on all parts of the plants. The injury which initiates them may be an abrasion, puncture or Fungus infection—but the minute wound or other disturbance, instead of healing over normally, is frequently maintained as a permanent irritation of the cells by mycelia. These hairs, often occur in tufts, and are so coloured and arranged that they were long taken for Fungi and placed in the "genus" Erineum. Cecidia or galls arise by the hyperrophy of the subepidermal cells of a leaf, cortex, &c., which has been pierced by the oviposition of an insect, and in which the egg is deposited. The irritation set up by the hatching egg and its resulting larva appears to be the stimulus to development, not a poison or enzyme injected by the insect. The extraordinary forms, colours and textures of the true galls have always formed some of the most interesting of biological questions, for not only is there definite co-operation between the gall-forming insect and the gall-producing fungus, but it appears that the same insect may initiate galls of different kinds on different plants or organs, while different insects induce different galls on the same plant—e.g. the numerous galls on the oak—but the galls of different origins are usually and often strikingly similar in growth, structure, and nutriment to its particular larva, and often appears to be without injury to the plant. The latter fact is no doubt due to the production of an excess of plant materials over and above what is needed for the growth of the insect; the sense—technically Cecidia—are not always due to insects. The nodules on the roots of leguminous plants are induced by the presence of a tryphine organism known to do no injury to the plant. Those on turnips and other Cruciferous are due to the infection of Plasmodiophora, a dangerously parasitic Myxomecete. Nodules due to "eel-worms" (Nematodes) are produced on numerous cultivated plants, both tuberous and succulent, in groups resembling those of tomatoes, cucumbers, &c., and the only too well known Phyloxtera, which cost France and other vine-growing countries many millions sterling, is another case point. Fungi galls on leaves and stems are also known, but not commonly met with by plant pathologists. The black blistering swellings of Ultagis Maydes, the yellow swellings on nettles due to Acidium, &c., in many cases the swellings on leaves of maize, and may be termed asexual, due to Aphis cyntherea, many Utillagineae, &c. These cases are not easily distinguished superficially from the pustular outgrowth of actual mycelia and spores (stromata) of such Fungi as Nectria, Puccinia, &c. The cylinder galls of plants, due to Cylindrocladium, also be mentioned here, and the tyro may easily confound with these the layers and cushions of eggs laid on similar organs by many of gall-flies, &c., which are peculiar and individual, which no external cause has as yet been determined, and which are therefore often ascribed to internal causes of disease. Such are the cork-warts on elms, maples, &c., and the class of outgrowths known as Intumesences. Recent research points to definite external conditions of moisture, affecting the processes of respiration and transpiration, &c., as being responsible for some of these. The "scab" of potatoes is another case in point. Frost blisters are peculiar swellings due to the upgrowth of callus-tissue into cavities caused by the bursting of the superficial cortex under the action of intense cold.

Turning now to outgrowths of a woody nature, the well-known "burls" are common on elms and other trees are cases in point. They are due to some injury—e.g. bruising by a cart-wheel, insects—having started a callus on which adventitious buds arise. The origin of buds at the base of a branch, store of food-material being accumulated at the injured place, other buds arise at the base of or around the injured one. If matters are propitious to the development of these buds, then a tuft of twigs is formed, a so-called "burl," but if they are arrested at an early stage, new buds are again formed, and in larger numbers than before, and the continued repetition of these processes leads to a sort of conglomerate woody mass of fused bud-bases, not unlike the outer bulbs of a "turf." When large, and the crowded portion of woody material as it slowly grows. There are many varieties of burls, though all woody outgrowths of old trees are not to be confounded with them, e.g. the "knots" of texture and the "brags" of burrs are not to be confounded with "burls," and the woody "wicks" and "brons," with all the twigs arrested to extremely short outgrowths. Witches'-brooms are the tufted bunches of twigs found on silver fir, bitches and other trees, and often present resemblances to birds'-nests or clumps of mistletoe. It only seen from a distance.
